In the Pacific West there is a land problem of particular urgency. In 1936 alone, conservative checks and estimates indicate that 10 000 additional families sought settlement on the land in Washington, Oregon, Idaho, and Western Montana. Similar checks and estimates for the first half of 1937 indicate that the totals for that year will be even larger than in 1936. Various factors, such as climatic and economic conditions and age composition of populations elsewhere as well as past trends, indicate that such westward migrations are likely to continue. Of course, all these rural migrants will not settle on irrigated land, although the majority undoubtedly would do so if opportunity offered; but in two years, allowing only 40 acres per family, there were enough migrants to settle the equivalent of about one-seventh of all the feasibly irrigable land in the region to which they have come. In other words, there was a sufficient number of families in two years to settle the equivalent of at least two-thirds of the land of the Grand Coulee reclamation project, which may require twenty years for completion. It might be added that, lacking a comprehensive program of land reclamation, less than 20% of the immigrant farm families in the Pacific Northwest in 1936 were able to settle permanently on economic farm units.

[69] "Regional Planning," Pt. 1, "The Pacific Northwest" (Columbia Basin Rept.), National Resources Committee, 1936.

[70] Rept. of National Resources Board, December, 1934; also, Supplementary Rept. of the Land Planning Committee.

[71] "Irrigation and the Land-Use Program," by John W. Haw, *Civil Engineering*, October, 1936, p. 663.

Additional factors affecting the economics of Western public works lie in the national ownership of a large part of the land resources. (More than one-half the land area of the eleven Western States is in Federal ownership.)

Hydro-electric power is one of the outstanding resources of the Pacific Northwest, which contains about 40% of the potential hydro-electric power in the United States. The wise and the earliest practicable economic utilization of this non-exhausting natural resource is naturally of great importance to the people of this region and to the nation. In round figures, the potential hydro-electric power capacity of the Pacific Northwest is about 16 000 000 kw. The developed power capacity is about 1 800 000 kw for four States—Washington, Oregon, Idaho, and Montana. The initial capacity at Bonneville (two units) will add 86 400 kw, and the ultimate added at Bonneville will be approximately 500 000 kw. The initial capacity at Grand Coulee will probably be 315 000 kw, and the ultimate planned is 1 890 000 kw. In round figures, the production (four States), in kilowatt-hours, increased from a negligible amount in 1909 to 900 000 000 in 1910, to 3 000 000 000 in 1920; and to 6 000 000 000 in 1929. Following a drop below 5 000 000 000 in 1932, production again advanced to nearly 7 500 000 000 in 1937. The probable production, on the completion of Bonneville, Grand Coulee, and other plants, now under way or planned (1938), will be about 18 000 000 000 kw-hr. Curves of power consumption may be projected into the future on one's own optimistic, pessimistic, or average basis; neither future compounding rate of increase, rate of diminution of the compounding rate, nor the ceiling level can be estimated with any certainty. So many factors are involved that projection of any one curve for more than two decades or so is scarcely warranted; it would be more realistic to try and estimate curves marking upper and lower limits for such long-range use. In any case, however, it should be apparent that there are still many potentialities for expanded and new uses of electric energy, that saturation is not yet in sight, and that if the country advances at all—that is, barring economic ineptitude on the part of the nation and its people—the power will be used, and probably during a time not inconsistent with the probable rate of completion of the current Columbia River power projects.

With reference to Bonneville, the Oregon State Planning Board has conservatively estimated that the assumed Oregon half of Bonneville's ultimate capacity will be absorbed by its Oregon market area, and that 200 000 kw more will be required in sections of the State outside the Columbia Basin area by 1946.[72]

The power projects in the Pacific Northwest should be considered also as potential keys to a needed broader industrial development and a better-balanced regional economy. Complete self-sufficiency is not thought of as a desirable or practical ideal, but studies indicate, for the Pacific Northwest, a marked deficiency in manufacturing activity and a tendency to "live off" of capital through primary economic dependence upon extraction of regional resources which are not readily replaceable—primarily those of soil, forests, and minerals. The fundamental condition, which indicates a flow of wealth to the industrial and financial centers of the East, may be seen at a glance in Fig. 1 which shows the net values of various classes of imports to, and exports from, the region. For a secure region and a secure nation there must be an adequate return flow of wealth. Public works is one of the means of bringing about such a flow. If these public works tend to provide for improvement of the economy of the region, as well as for an immediate return of wealth, so much the better. Abundant and low-cost power, tending to increase industrial activity, payrolls, and dividends, should be highly important to the Northwest economy.

---

[72] "Use of Electricity in Oregon with Forecasts of Future Demands," Oregon State Planning Board, September, 1936.

Incidentally, another form of return flow of wealth is tourist travel, which, it will be noted, is also somewhat related to public works through highway construction, national park, and national forest programs.

The Pacific Northwest is one of the regions in which inland navigation is of high present and potential importance. The regional freight rates are among the highest in the United States. Further economic transportation development will be essential to the general development of the region. Modern trunk inland navigation is an important corollary of the land, power, and industrial developments. Both East-and-West and North-and-South trunk lines are feasible from the engineering standpoint. Providing efficient transportation for bulk materials in particular, inland waterway improvements, as found economically feasible, will aid in the further utilization of regional resources. The juxtaposition of economical power and ocean navigation in the Lower and Middle Columbia River is particularly significant. Furthermore, navigation is one of the multiple uses of the water resources that, together, make large-scale development economically feasible.

In connection with multiple water use it should be noted that the Grand Coulee Project, with its more than 5 000 000 acre-ft of useful storage, will provide, in addition to reclamation and power, general benefits in river regulation—primarily, in increasing ultimate efficiency of all down-stream power plants and, secondarily, in flood control and river navigation.

There are other large projects[73] in the Pacific Northwest in various stages of development; for example: Various water conservation and irrigation projects in Washington, Oregon, Idaho, and Montana; further projects in the comprehensive plan for the Lower and Middle Columbia and Snake Rivers; and the Willamette Valley project in Oregon. (Comprehensive studies and reports on this last-mentioned multiple-use project have been made by the Corps of Engineers, U. S. Army, and by the Oregon State Planning Board.)

It is strongly believed that there must be a place in any long-term public works program for the large projects of this character. It is also believed that matters of law and appropriation, rather than demonstration of sound economics, will in most cases be the last hurdle to be topped in getting them under way. Properly conceived, such projects have far greater and more lasting economic effects than small, unrelated public works projects. Ranking in economic importance with the large projects are well co-ordinated programs of smaller public works (for example, such programs as that of the Montana Water Con-

---

[73] "Drainage Basin Problems and Programs," National Resources Committee, 1936–1937.

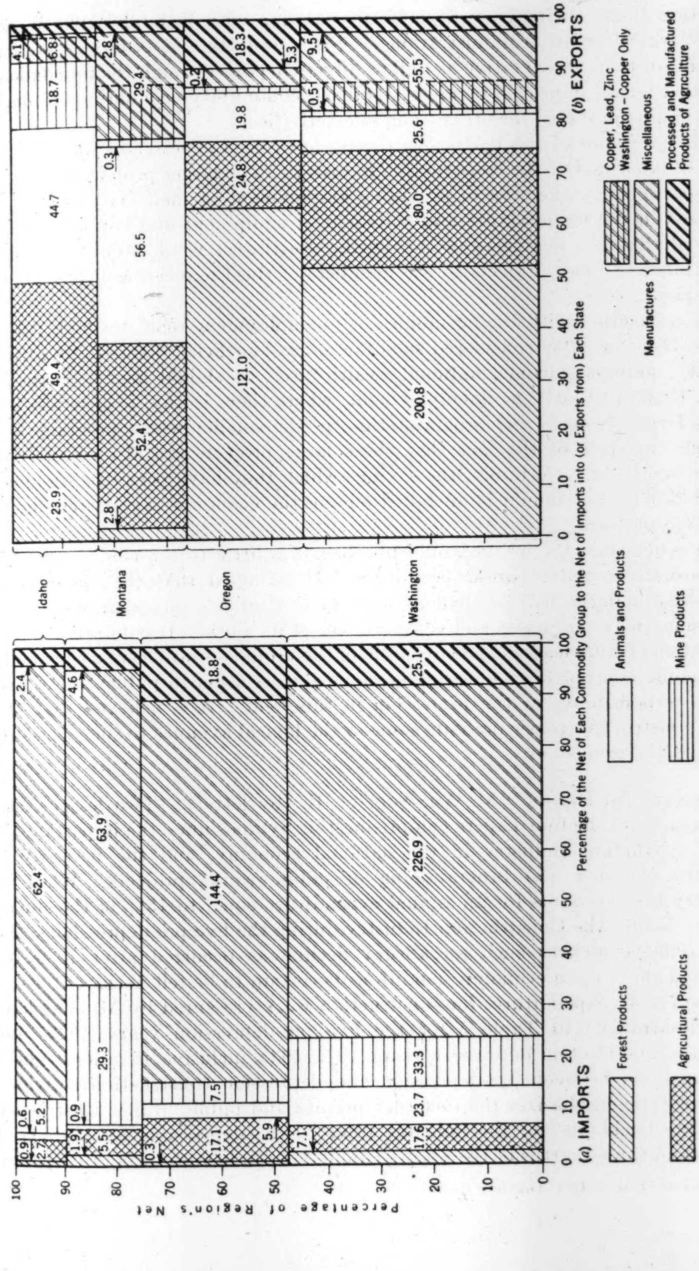

FIG. 1.—ESTIMATED VALUE OF APPARENT NET IMPORTS AND EXPORTS OF THOSE COMMODITIES SHOWING AN IMPORT (AND EXPORT) BALANCE IN THE EXTERNAL TRADES OF THE PACIFIC NORTHWEST STATES, 1929

servation Board, being carried on in co-operation with Federal Public Works and Works Progress Administrations). Such projects and programs are important for their regenerative as well as direct effects—through the foundations provided for an improved or more stabilized community economy or through the stimulus provided for other economic activities.

The programs of the Pacific Northwest have been effective in the employment of labor and of the construction industry. The larger projects have also been particularly effective in providing employment of men and industry in the East in the manufacture and shipment of equipment and supplies. It is believed that few engineers of the Pacific Northwest would doubt the vital importance of these projects to the members of the Engineering Profession in the region.

In connection with the economics of unemployment relief through public works, there must be considered such factors as beneficial effects in industrial activity, national income, national wealth, etc. It should also be borne in mind, that "write-off" to unemployment, where there is any, is generally less in the larger projects and programs than in the smaller works programs and projects, in spite of the fact that these large projects are also effective in emergency relief. Certainly, the savings which they have permitted in direct and indirect relief should be included among the economic factors relating to the large projects.

In conclusion, the writer would like to add a little to the challenge of the Symposium on public works economics. It is hoped that the Engineering Profession at large will be challenged to give a greater consideration to the economic and social bases and consequences of its work. It is hoped that the present and future leaders and educators of the profession will have a constantly broadening concept of engineering economics in relation to public works, and of the responsibility of the profession in this field. It is believed that Mr. Fay's constructive paper presents some of the logical avenues to such consideration by the profession.

DONALD M. BAKER,[74] M. AM. SOC. C. E. (by letter).—Two lessons may be drawn from the four papers comprising this Symposium—the importance of the Construction Industry in the national economy, and the necessity of advance planning and programming of public works projects. When an industry that accounts for an annual expenditure equal to 15% of the annual income (as did the Construction Industry during the five pre-depression years, 1925–1929) evidences such an abrupt decline as occurred after 1930, the resulting effect upon economic conditions is certain to be felt keenly.

Data as to expenditures for construction work presented by Mr. Fay have been re-arranged in Table 5 for the five pre-depression years, 1925–1929, inclusive, and the four depression years, 1932–1935, inclusive, in order to afford a comparison between pre-depression and depression construction activities. This analysis emphasizes the fact that private and public utility construction was the "backbone" of the industry prior to the depression, accounting for more than three-fourths of the average annual expenditures during that period.

---

[74] Cons. Engr., Los Angeles, Calif.

In spite of largely increased public expenditures during the four depression years, public utilities accounted for one-third of the expenditures, and private construction for one-fifth.

TABLE 5.—ANALYSIS OF CONSTRUCTION EXPENDITURES, 1925–1934

Agency	AVERAGE ANNUAL EXPENDITURES, 1925–1929			AVERAGE ANNUAL EXPENDITURES, 1932–1935			PER CAPITA EXPENDITURES, IN DOLLARS		Ratio, Column (4)/Column (1)
	Millions of dollars (1)	Percentage of totals (2)	Percentage of public works (3)	Millions of dollars (4)	Percentage of totals (5)	Percentage of public works (6)	1925–1929 (7)	1932–1935 (8)	(9)
Public Works:									
Cities	1 364	11.5	4 .2	563	13.3	29.0	11.54	4.47	0.413
Counties	746	6.3	26.4	125	3.0	6.4	6.31	0.99	0.168
State	466	3.9	16.5	450	10.7	23.2	3.94	3.57	0.966
Federal	252	2.1	8.9	802	19.0	41.4	2.13	6.36	3.185
Totals:

Grand total	11 900	100.0	420.0	4 220	100.0	217.5	100.62	33.49	0.355
Total, private plus public utilities	9 072	76.2	320.8	2 280	54.0	117.5	76.70	18.10	0.251
Average, annual national income	78 343	....	....	46 472	....	....	....	....	0.592
Average annual per capita income	663	....	....	368	....	....	....	....	0.552

The greatest proportionate reduction in expenditures occurred in those made by private agencies and by counties, where they fell to about one-sixth of pre-depression rates. Activities of cities and public utilities were reduced three-fifths, those of States showed a slight decrease, and those of the Federal Government increased threefold. In spite of the increased Federal expenditures, public works decreased one-third, and total construction activities were reduced to about one-third of the pre-depression rate.

Data in Table 6, taken from 257 identical cities, indicate that the great reduction in private construction was probably due in large measure to the almost complete cessation of residential building, which was caused by widespread unemployment, reduced incomes, and uncertainty as to the future of those still employed. Counties usually carry on their construction programs from current revenues received from taxation. Deflation of assessed values during the early years of the depression no doubt had a telling effect upon

TABLE 6.—BUILDING CONSTRUCTION IN 257 IDENTICAL CITIES

Description	1925–1929	1932–1935	Ratio, 1932–1935/1925–1929
New residential construction per year	$1 983 217 000	$120 777 000	0.0608
Families provided for per year	398 521	32 784	0.0822
Expenditures per family	$4 975	$3 692	0.7420
Total building construction, including additions, alterations, repairs, and other buildings per year	$3 516 282 000	$473 922 000	0.1347

revenues, and the necessity of caring for the local relief load as well as maintaining other functions of county government left little surplus for public works projects. A considerable proportion of the construction expenditures of both cities and public utilities usually goes for expansion of facilities to care for increase in population. The "back to the land" movement, which was very active during the early years of the depression, slowed down urban population increase to a great degree, and both city and public utility construction was probably gaged closely to that necessary for operation and maintenance.

A very large proportion of State expenditures is for highways, financed by gasoline and motor vehicle taxes, and bond issues. Since people still operated their automobiles during the depression, and a large State bond issue takes considerable time to spend, it could be expected that State expenditures for construction would be maintained. In the light of what occurred there remained no agency other than the Federal Government financially able to make an attempt to support the Construction Industry. It was as unprepared to embark upon a large program of public works as it was to enter the World War in 1917; but so was nearly every other agency engaged in construction, except possibly the various States, which, in general, have developed the practice of advance planning and programming of highways, because of the certainty of future income. City planning has become a recognized function of many city governments since 1920, but most city planning boards or commissions have either become involved in the complexities of zoning, or if they have developed anything approaching a comprehensive city plan, have given little attention or thought to the financial or timing aspects of achieving it.

Considerable criticism is offered in the papers of the Symposium to the economic aspects of certain large public works projects embraced in the Federal program. Although not attempting to defend any of the projects referred to, the writer would like to call attention to several facts which must be borne in mind when they are being discussed. These facts are:

(*a*) Lack of preparedness and of planning always causes waste, in public works programs, war, or other activities.

(*b*) Public works projects are seldom initiated or promoted by politicians or public officials. They are usually conceived, and in their early stages promoted, by local interests that expect, individually, to benefit by their construction or operation. This, in itself, is not at all reprehensible in the case of sound projects. Were this not the practice, there would be a far less number of worth while public works projects. These local interests include engineers, architects, material and supply firms, contractors, land-owners, industrialists, financiers, etc., acting individually or through Chambers of Commerce, Boards of Trade, and professional or trade associations. The project is then "sold" to the local public, and becomes a local issue. Once it attains this status, politicians and public officials, under the influence of pressure groups, adopt and support it. Let them question the need or economic feasibility of the project, and other aspirants for public office will be found in large numbers ready to come forward with offers of support if given an opportunity to occupy public office. The writer agrees with the opening statement of Professor Mead that "a well informed public can and will raise such objection to projects which they know to be unsound that no Federal, State, or Municipal Administration will dare to undertake such projects," but wonders how the public is to be informed. He knows of instances where individual engineers and engineering organizations—even Sections of the Society—have expressed disapproval of the economic feasibility of public works projects in serious and carefully prepared reports, only to have their voices drowned out by the loud acclaim of the local public (not the politicians and public officials), this acclaim, in many cases, being based upon other favorable reports made by engineers. There may be some satisfaction in keeping the record clean, even if it is buried, but until engineers learn to adopt the technique of the promoters in gaining a public audience for their conclusions upon uneconomic public works projects, their influence in heading off such projects will be little felt.

(*c*) The amount of attention paid to the economic feasibility or need of any public works project by the general public of a community benefited by its construction or operation is usually in the inverse ratio to the proportionate cost of the project, or of its operation paid by the community. Projects financed by local taxation or bond issues primarily are likely to be widely discussed, pro and con, and criticisms of unwise projects usually find an audience. However, where costs are borne indirectly to a large extent, or are met from a distant source, the customary tendency is not to "look a gift horse in the mouth." This points to the advisability of local participation to the greatest degree possible in the costs of public works projects.

Fig. 2 shows the cumulative expenditures for construction for the 11-yr period, 1925 to 1935, inclusive, according to various classifications as given by Mr. Fay in Tables 1 to 3, and indicates a deficiency in expenditures by 1935 of $36 760 000 000 based upon the pre-depression rate of $11 900 000 000 per yr; or $100.62 per capita per yr. This deficit is classified as follows:

Public works	$ 3 150 000 000
Private	23 480 000 000
Public utilities	10 130 000 000
Total	$36 760 000 000

and would indicate annual expenditures of the order of $16 000 000 000 for the 10 yr following 1935 if the deficit is to be overcome and the pre-depression rate resumed. The writer is inclined to believe, however, that the pre-depression rate of $100.62 per capita was artificially stimulated by rapid increase in urban population and an urgent need to supply the population of the nation with a greatly increased standard of living. On the basis of a national population increase of 7 224 000 during that 5-yr period, it meant an expenditure of $8 240 for each person added to the population. However future construction expenditures are computed, they will be large, and the great probability is that those allocated to public works will embrace a continually increasing proportion. This trend was well established prior to the depression and has been greatly fostered during depression years, and such trends are persistent.

Since all construction work is undertaken to serve one or more of the following purposes: (*a*) To replace existing facilities which have worn out or become obsolete; (*b*) to provide new facilities to care for increases in population; and (*c*) to provide new facilities necessary to increase the standards and conveniences of living, it is probable that an analysis of construction expenditures made during the five pre-depression years would show that many of them were made for Purposes (*b*) and (*c*). Indications are to the effect that the trend toward further urbanization, so strong during the 1920–1930 decade, may slacken in the future. This trend, with an approach to stationary national population and a probable reduction of westward migration, would indicate that future construction will be made primarily to serve Purposes (*a*) and (*c*).

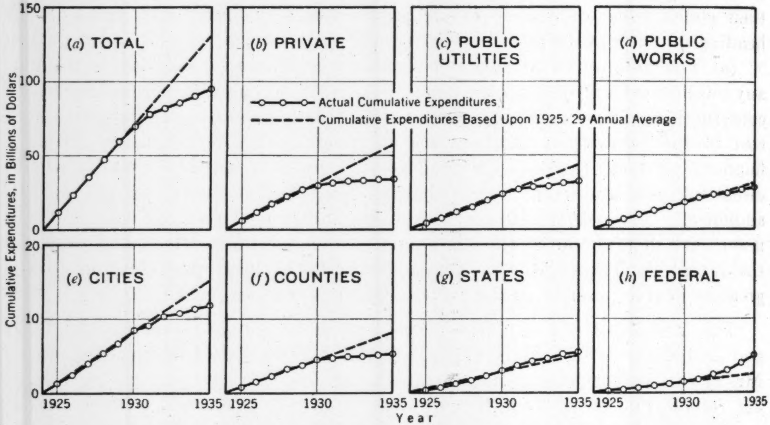

FIG. 2.—EXPENDITURES FOR CONSTRUCTION, 1925–1935

If, as it would appear, a large program of public works construction is indicated in the future, the matter of planning and programming in connection with such program takes on added importance. Such activities must be conducted not only on a national basis, but by State and local agencies. Strictly speaking, they fall into two phases:

(1) The development of physical plans for public works projects, which will result in an effective and efficient utilization and control of natural resources for the public benefit, or will serve the convenience and necessity of the general public; and,

(2) The development of a program for the initiation and completion of these projects which will bring them into existence or operation at such times that increasing public needs and requirements will be satisfied, will keep costs of the projects within the reasonable financial ability of those benefited by and paying for them, and will provide for the allocation of such costs equitably among those benefited.

The first phase is essentially within the province of the engineer, and he has, when engaged in it, acquitted himself with great credit, often under difficult circumstances. The second phase, that of programming, which involves forecasting future needs and requirements, is far more difficult. Although it involves engineering ability and judgment of the highest order, it also requires knowledge and judgment in other fields, including economics, sociology, politics, industry, human nature and habits, geography, and even history. The development of leadership in this phase by engineers affords an opportunity to the Engineering Profession second to none that has occurred heretofore.

In illustration of what is meant by the foregoing two phases of activity in public works planning, consider the case of a large drainage basin which offers possibilities of development for hydro-electric power, irrigation, domestic water supply, and recreation. It is one thing for an engineer to prepare plans and make designs for the various dams, conduits, power-houses, transmission lines, etc., and to build them; but it is another thing for him to plan these structures of proper sizes and to recommend the date for their construction at such times that, when they are placed in operation, fixed charges for unused capacity will not be burdensome, that demands for their services can be met, and that costs will be allocated equitably among those benefited or served. The writer has noticed a tendency on the part of too many engineers to devote 90% of the contents of their reports to the subject of physical plans, and only 10% to the program of development, allocation of costs, etc.

Because of changes that occurred during the 1920–1930 decade, and which will occur because of the depression, it will be more difficult to make predictions of future needs and requirements than in the past. Indications are that many trend curves developed a point of discontinuity about the year 1930.

The problem of national population is an excellent example. Forecasts of probable national population increase[75] indicate a numerical growth between 1930 and 1960 (30 years) but slightly in excess of that which occurred during the 10-yr period, 1920 to 1930. In 1960, it is estimated that 42% of the population will be more than 40 yr of age, as against only 28% in 1930. The effect of this upon habits, needs, and methods of living must be considered. During the 1920–1930 decade the population of urban places increased 27%, whereas it is estimated that during the three decades, 1930–1960, even maintaining the rate of migration to urban areas that occurred during 1920–1930, the total increase in population will be only 19.5%, or 6.5% per decade. If these forecasts are correct, the effect upon such construction activities as residential building, public utilities, etc., will be pronounced. Migration of people has always been a far more important factor in population increase in the Western States than natural increase. This migration follows a law similar to that of Ohm's law in electricity—the rate of migration varies directly with differences in economic pressure at its origin and its destination, and inversely with the resistance to the movement of people. People move away from places where opportunities are few and where it is difficult to make a living, to places where opportunities are greater and living easier, provided they can get away. During the depression the "difference in potential" between the East and the West has been greatly reduced, and the difficulty of getting away and starting to move has increased. Whether these conditions are permanent or temporary is something that is still not clear, but it should be considered seriously by those making long-range programs of public works.

---

[75] Rept. of National Resources Committee, 1934–1935, pp. 95–97.

Another factor that must be appreciated and considered in making programs is the fact that curves of per capita production and consumption of many of those things which go to the improvement of standards and conveniences of living are showing tendencies to flatten out, indicating a condition of approaching saturation and a probable future production and consumption, at a rate of increase more closely paralleling that of increase in population. The data in Table 7 are illustrative of this point.

TABLE 7.—RELATION BETWEEN CONSUMPTION AND POPULATION INCREASE

Description	1920	1925	1930	1935
Electric power consumption, in kilowatt-hour per capita	408	573	778	....
Motor vehicles per 1 000 population	87	174	215	....
Telephones (Bell System) per 1 000 population	111	139	163	....
Radios per 1 000 population	....	....	109	169

These factors have had a most important effect upon the thinking and living habits of the American people, and were no doubt responsible to a considerable extent for the pre-depression construction activities.

There is no reason why the engineer should not assume leadership not only in planning but in programming public works projects; in fact, there is every reason why he should, but he must realize, when he attempts to do so, that technical engineering is only a part of his work, and if he enters this phase, he must be ready to assume the blame when the projects for which he is responsible develop into economic failures, when judged by proper standards, just as he now assumes the blame for physical failures.

PHILIP W. HENRY,[76] M. AM. SOC. C. E. (by letter).—Among the "notable examples of admirably run publicly-owned" revenue-producing enterprises, Colonel Wilgus cites the municipal subways owned and operated by the City of New York, N. Y., but he does not mention that they are not earning interest charges. The original rapid transit systems (elevated railways and subways) were built by private capital on which they made a reasonable return; but no capitalist would have under-written the municipal subways which have not only failed to earn interest, but, through competition, have greatly decreased the earnings of privately-owned subways. Had the City of New York left the transit field to private capital, it would not now be levying a 2% sales tax and looking around for other methods of taxation in order to balance its budget. In building subways the City Government was no more interested in the economic aspects of the case than was the Federal Government when it authorized the construction of Bonneville, Fort Peck, Grand Coulee, and other projects.

The capitalist asks of a given project: "Will it make a return in dividends?" The politician asks: "Will it make a return in votes?" Under the capitalistic system Americans have attained the highest standard of living known to history. Under the political system, if adopted generally, they will see this standard stationary or even lowered.

---

[76] Cons. Engr., New York, N. Y.

H. K. Barrows,[77] M. Am. Soc. C. E. (by letter).—The papers by Messrs. Riggs and Wilgus contain much that is of interest. The various public works projects, including Passamaquoddy, Fort Peck, Bonneville, Grand Coulee, and the Florida Ship Canal, have all been given thoughtul attention and a clear picture presented of their nature, cost, and economic status.

From the taxpayers' viewpoint, only one of them (Bonneville) appears to have any chance of being classified as a project justifiable in character and as a wise expenditure of public funds.

As has been emphasized, it is the function and duty of Congress to see that proper use is made of Federal funds. In considering these projects the situation was somewhat involved because of their association with relief work. Such large and expensive projects, with their usefulness far in the future, if at all, are obviously not a proper class of undertaking for relief work.

The authors of the Symposium papers have brought the situation to the attention of engineers, and, in so doing, have also reached the public to some extent. It is the latter who should understand the situation, so that the people may express to their Congressmen their disapproval of such unworthy and undesirable projects. This work of education must begin at home, and engineers, who understand what these projects are and mean, have an individual duty in acquainting the layman with the facts, so that such unwise projects may be avoided if possible in the future. As Professor Riggs, in closing, states: "They will fail in their duty if they keep silence."

Harry A. Wiersema,[78] M. Am. Soc. C. E. (by letter).—In his paper in this Symposium, Mr. Mead has given a brief analysis of several Government projects, including the Tennessee Valley Authority (TVA), and has drawn a conclusion regarding the latter which is far from complimentary. He states (see heading "Government Interference as a Permanent Policy: Responsibility of the Engineering Profession") that he has nothing to criticize with regard to the engineering features of the TVA, but gives the principle that "sound engineering cannot make an uneconomical project an economic success." The writer is entirely in accord with this principle, but he is so at variance with the conclusions regarding the economic feasibility of the TVA project that some discussion of this subject seems desirable.

The highest standard of ethical conduct should actuate all engineers in Government service, and to the extent that it does not such engineers are not true to their profession. It is not enough that an engineer render a high quality of technical service, but he also has a responsibility to the public for rendering the same kind of service that a consulting engineer would render to a private client in determining the economic feasibility of the project entrusted to his care. An engineer entering the service of the TVA would be confronted by a situation which might be compared to the relationship between a client and his engineer. In the following theoretical conversation, the United States Government has been personified to represent the client, who is setting out his plans and purposes to his engineer:

---

[77] Prof., Hydr. Eng., Mass. Inst. Tech.; and Cons. Engr., Boston, Mass.

[78] Gen. Office Engr., TVA, Knoxville, Tenn.

"Many years ago, spurred on by the necessity for the manufacture of munitions during the great war, I made an investment in a hydro-electric development at Muscle Shoals which has been a financial failure. In the first place, the actual sum of money expended in the construction of this project was much greater than it should have been, due to many factors, including the abnormally high price levels obtaining during the initial construction period and due to the prolonged and interrupted construction period. In accordance with the direction[79] of the Congress, the Tennessee Valley Authority submitted a valuation of Wilson Dam of $31 300 000 which was approved by the President on May 6, 1937. In the second place, due to the fact that this is an isolated plant and that there are no facilities for marketing the power, the income has been insignificant, represented only by sales to a single public utility company at a figure of 2 mills per kw-hr, which was the best I could do in such a monopoly market. The amounts of power thus sold were entirely at the discretion of the buyer, and only about one-fourth of the possible output was actually disposed of. I did receive several offers for the purchase of this plant, none of which was acceptable.

"I believe that the only way to save any considerable part of this investment is to develop further the resources of the Tennessee River. Congress has already recognized the potential value of the Tennessee River as an inland waterway by approving a plan for providing a 9-ft navigable channel from Knoxville to the mouth of the river, a distance of 650 miles. Wilson Dam forms an integral part of this plan. The Tennessee River and its tributaries have a considerable flow at time of flood, and it is desirable to provide flood-control projects on this river to assist in protection against floods, both locally on the Tennessee River and on the Lower Mississippi River. I believe that it is possible to develop a series of projects on this river system which will provide the waterway desired by Congress, together with a substantial degree of flood control, and at the same time develop considerable of the potential water power of the stream. In an integrated system of dams, the surplus power at each lower river project is increased by the released storage from plants above. If this water power can be converted into electricity and sold, the income from such sales will go far toward returning the cost of the entire development.

"The Army Engineers have already constructed the lock for a dam at Wheeler, the next location above the existing Wilson plant, so that the navigation program is already under way. Now is a most favorable time for public works construction; Government credit is at its peak, and long-term money can be obtained at very low interest rates. There is a distinct advantage in constructing public works during times such as these when there is considerable unemployment. Such a development will not only effect an immediate improvement of economic conditions in a large section of the country but will also result in permanent additions to the nation's wealth. In addition to these considerations, we will have in this project a welcome experiment in integrated control of an entire water-shed, involving conservation of natural resources, broad scale regional planning, and an opportunity to demonstrate the advantages of a wider and better use of electricity."

There are several points of view which might be adopted with regard to the validity of the Authority's projects. For example, that part of the work which is justified for flood control and navigation could be considered as non-income producing public works; or the entire project could be considered as semi-revenue producing public works, and allocation of costs made to the different benefits. However, in order not to confuse the issue as to the economic justification of the Authority's projects by entering into a controversy regarding "yardsticks" and "allocations," it seems desirable to make an analysis similar to that made by Mr. Mead to determine how much of the total investment can be liquidated by the sale of surplus power. The following study is such an analysis of the economic feasibility of the project, based on conservative estimates of revenues from the sale of hydro-electric power, and actual project estimates which are fairly definitely determined. It is based on the system that will be developed when dams now (1938) under construction will be finished, which will be by January 1, 1942, rather than on the 11-dam system used by Mr. Mead. The 11-dam system has not yet been approved by Congress and the estimates are, therefore, approximate; for the 7-dam project, on the other hand, Congressional authorization has been fully obtained and estimates of cost and power can be much more accurately determined. The estimated cost of these seven dams[80] is shown in Table 8.

---

[79] TVA Act of 1933, Section 14.

TABLE 8.—ESTIMATED COST OF SEVEN PROJECTS, TENNESSEE VALLEY AUTHORITY

Item No.	Project (1)	Initial power installation, in thousands of kilowatts (2)	Estimated cost of initial stage (3)	Item No.	Project (1)	Initial power installation, in thousands of kilowatts (2)	Estimated cost of initial stage (3)
1	Wilson	184	$31 300 000	5	Guntersville	72	$36 334 720
2	Norris	100	36 361 738	6	Chickamauga	81	43 127 903
3	Wheeler	128	36 849 403	7	Hiwassee	60	21 529 579
4	Pickwick Landing	72	33 219 279				
				8	Total	697	$238 722 622

Except for the Wilson Dam (see Item No. 1, Table 8), which is a valuation determined by Congress, these estimates are carefully prepared and contain conservative sums for construction contingencies. Two of the projects, Norris and Wheeler, were finished slightly under these estimates in 1936 and in none of them is there any question of returning to Congress for additional funds to make up deficits, even in the face of increased labor and material costs.

The actual sums spent for transmission lines and sub-stations through the fiscal year 1937, together with the budget estimates for the fiscal years 1938 and 1939, are as follows:

Period	Expenditure
Prior to July 1, 1937	$11 323 182
Budget, fiscal year 1938	5 740 000
Budget, fiscal year 1939	5 560 000
Estimated additions to January 1, 1942	12 500 000
Total (say, $35 000 000)	$35 123 182

An amount has been added for additional investment up to January 1, 1942, which is approximately proportionate to the existing rate of expenditure and which, it is felt, under existing conditions, is adequate to provide a transmission system capable of disposing of the entire power output that will be available as of that date.

---

[80] Rept. of Hearings on the Independent Offices Appropriation Bill for 1939, 75th Cong., 2d Session, p. 919.

When the estimated cost of transmission facilities is added to that of the hydro-electric projects, the total investment as of January 1, 1942, becomes $273 722 622.

It is well to note that the estimate of the total project cost is based on the actual system being constructed. This system is the most desirable from the standpoint of a multi-purpose development, but it is not the most desirable from the standpoint of hydro-electric power alone. If the TVA had planned its projects for power as a single purpose and for the maximum dollar net income, there are other more economical power projects in the Valley which would have been substituted.

The fixed charges constitute by far the largest portion of the total annual cost of such projects, and these charges would reasonably be computed on the basis of the average interest paid by the Government on long-term bonds. Over a long period of years the average interest rate on borrowings by the Federal Government has been less than 3%, and in the period from 1933 to 1938 Government interest rates have been at an especially low level. The Federal Power Commission has determined the weighted average rate on all borrowings of the United States Government from November 1, 1933, to December 31, 1937, to be 1.54271%; but it would be difficult to justify so low a rate of interest in measuring the feasibility of the TVA program. The "Baby Bonds" that are sold to the general public are computed to yield an interest rate of 2.9% over a long period of years, and it appears to the writer that this constitutes a fair basis for amortizing the project.

The life expectancy of the various classes of property included in this project varies widely, ranging from less than 20 yr in the case of certain parts of the transmission system to an indefinite life in the case of reservoir lands. Giving consideration to the portion of the total investment represented by reservoir lands and long-life concrete structures (which will be more than one-half the total cost of the project) it is felt that a service life of as much as 75 or 80 yr is not an unreasonable expectancy. However, in order to adopt a conservative value for the purpose of the present discussion, a 50-yr over-all expectancy has been used. Based on a 50-yr life and an interest rate of 2.9%, the sinking-fund method of calculating annual depreciation charges results in a depreciation rate of 0.9%, or a total amortization rate of 3.8 per cent. Applying this to the total investment previously obtained, of $273 722 622, results in an annual cost for fixed expense of $10 401 450.

In order to determine the income from the sale of hydro-electric power, the best estimates available are those contained in the report given to Congress,[81] in which it is estimated that the demand for firm power in the year 1942 will be 480 000 kw, and for secondary power, 98 000 kw. The installed generating capacity in that year in the seven dams under consideration will be more than sufficient to provide for a total demand of this magnitude. A reasonable estimate of the energy sold with this demand would be about 2 600 000 000 kw-hr of primary and 650 000 000 kw-hr of secondary. Analysis of the capability of these seven projects shows that there is energy in excess of the total of the foregoing amounts after allowing for leakage, evaporation, utilization, and transmission losses, as well as efficiency losses in the structures and equipment. It should be noted that, were these projects to be operated for power only, instead of primarily in the interest of flood control and navigation, the potential available energy in these seven plants would be considerably greater than these amounts.

---

[81] Independent Offices Appropriation Bill for 1939, 75th Congress, 2d Session, p. 1000.

In estimating the annual revenue accruing from the sale of surplus power, the Authority's standard wholesale rate schedule may be used for firm power. Mr. Mead has quoted this schedule correctly with one exception. The schedule provides for a monthly reduction for energy used in excess of 360 times the billing demand of 0.5 mill per kw-hr from the otherwise applicable rate for such excess. The average rate under this schedule, estimated on a basis of weighted averages of the different sizes and types of load from existing customers, would be at least 4 mills per kw-hr, of which about one-half is represented by the demand charge and one-half by the energy charge.

The average rate for secondary power, as determined from the Authority's existing contracts, is somewhat in excess of 2 mills per kw-hr. The total operating revenue based on the sale of 2 600 000 000 kw-hr of primary energy at the minimum of 4 mills per kw-hr and 650 000 000 kw-hr of secondary energy at the minimum of 2 mills per kw-hr, is $11 700 000.

The Act creating the TVA provides for the payment to the respective States of 5% of the gross revenue received from the sale of power generated within their borders. This payment in 1942 would amount to $585 000.

The operating costs for this 7-dam system will consist of the cost of generation and transmission of electricity, cost of operating the locks, and certain expenses in connection with operating the reservoirs for flood control. The operation of the locks will be in the hands of the Army Engineers, and the estimate as to the cost of this operation is based on their experience. For the purpose of this analysis it appears desirable to make a comparison on two different bases: (1) Using only the cost of generating and transmitting power; and (2) using all the cost of operating the entire system.

Mr. Philip Sporn has given a table[82] of operating costs of hydro-electric plants, in which he shows that for plants of 50 000 to 100 000 kw of installed capacity the operating costs vary from a high of $1.50 to a low of 60 cents per kw, or a median of 75 cents, whereas, for larger plants the median is still lower. It is estimated that an average of 85 cents per kw would be a fair value. To this should be added the cost of operating the transmission system, and also an allowance for the cost of malaria control on the reservoirs (which, on account of the rather complete control that the Authority is instituting, will be a fairly large proportional sum). Adding these estimates, a value of $3.00 per kw of installed capacity appears to be conservative and reasonable, and this sum has been used in setting up the following tabulated estimate of revenue and expenses, as of January 1, 1942 (the estimates for additional expense for operating the system for navigation and flood control, including operation of the locks and certain required dredging, are also given):

---

[82] *Proceedings*, Am. Soc. C. E., December, 1937, p. 1927, Table 4.

Revenue and Expense	Per Annum	
Gross Revenue:		
Primary—2 600 000 000 kw-hr at $0.004 =	$10 400 000	
Secondary—650 000 000 kw-hr at 0.002 =	1 300 000	
Total gross revenue	$11 700 000	
Less payment to States at 5%	585 000	
Total revenue		$11 115 000
Expense of Operating Hydro-Electric Facilities:		
697 000 kw at $3.00 per kw		$ 2 091 000
Net revenue from power sales alone		$ 9 024 000
Additional Expense of Operation:		
Navigation facilities	$ 400 000	
Water control and land management	500 000	
Total		900 000
Total net revenue		$ 8 124 000

This tabulation shows that, based on operation of the power system alone, the net revenue would be $9 024 000, whereas based on the entire operation of the project the net revenue would be $8 124 000. Applying this revenue against the fixed costs, the revenue produced from the sale of power is 87% of the total fixed cost of $10 401 500 in the first instance, and even when all costs for operation for navigation and flood control are considered, the revenue is still 78% of the total fixed cost.

Reverting now to interest during construction, there are considerations that make this project unusual in this regard. For instance, the actual interest rates during the construction period have been extremely low and not much more than one-half the long-time average interest rate assumed, of 2.9%, so that the interest during construction will be a relatively small percentage of the total annual interest after the project is completed. As each dam is completed, it contributes to the power available for sale in an amount greater than necessary to carry its own interest, with a surplus to contribute to the interest on uncompleted dams. The income from the plants as they are completed prior to 1942 will so closely meet the total expense that it is certainly fair to assume that it will approximately offset the interest during construction; so that neither the factors of income nor interest during construction need be considered in this analysis.

As stated previously, the actual cost of capital to the Federal Government during the construction period of the TVA projects is not as high as 2.9% and, in fact, may be considered as low as 1.55 per cent. Accordingly, it would seem a safe conclusion that the TVA will liquidate practically all the Government's investment in the project during the life time of the physical structures through the sale of its surplus hydro-electric power.

This is a far different "picture" from that presented by Mr. Mead and justifies the faith of the Engineering Staff of the Authority in the economic feasibility of the project as a whole.

It might not be amiss to discuss the benefits from navigation and flood protection, intangible though they may be. The opinion expressed by Mr. Morgan,[16] that the project is worth all it will cost for navigation and flood protection alone, is shared by many engineers; and although it is impossible to analyze this benefit in the same way that the benefit from the sale of hydro-electric power can be analyzed, it is scarcely "so extreme that it seems useless to discuss it" (see heading, "Government Interference as a Permanent Policy: Power"). The Miami District of Ohio was designed and built for local protection only and could not be expected to contribute to flood protection on the Ohio River. The TVA System, on the other hand, is designed and built not only for flood protection on the Tennessee River but also for flood protection on the Ohio and Mississippi Rivers; and the Gilbertsville Reservoir, the farthest down-stream project of the TVA System, is especially valuable for this latter purpose. The U. S. Engineer Corps has allocated[83] to the Tennessee Basin a total flood storage of 10 589 100 acre-ft, of which the Gilbertsville Reservoir will provide 4 600 000 acre-ft with a possible addition of 1 450 000 acre-ft for extreme floods. The storage of this reservoir will reduce the discharge at Cairo by from 184 000 to 220 000 cu ft per sec, and Gen. J. L. Schley, U. S. Corps of Engineers, M. Am. Soc. C. E., has reported that this reservoir will reduce stages on the Mississippi River by 2 ft.[84] The value of this amount of reduction in providing protection to lands and improvements in the upper parts of the Mississippi River Basin has been estimated by Carl A. Bock,[85] M. Am. Soc. C. E., to be approximately $90 000 000. The estimate of $100 000 000 benefit for flood control of the entire TVA System, as made by Mr. Morgan,[16] would seem, therefore, to be fairly well justified.

The benefits from navigation are also intangible, but there is reason to believe that these benefits may be more than double the amount that Mr. Mead has estimated as justifying the expenditure of about $90 000 000.

From the foregoing analysis it is shown that the direct revenue from sale of hydro-electric power will liquidate all but 13% of the cost of the total investment. Applying this percentage to a total project cost of $500 000 000 would leave only $65 000 000 which is only one-half the sum that Mr. Mead himself estimates for the benefits of navigation and flood control, and only a small fraction of what may be the actual value of these benefits.

Whether or not the navigation and flood-control benefits are as great as Mr. Morgan has stated, and even if they are as low as Mr. Mead estimates, there can be no question that they are worth very much more than the actual unliquidated cost. Surely this is a thorough justification of the TVA program, and one of which its engineers may well be proud.

[83] House Doc. No. 259, 74th Cong., 1st Session.

[84] *Waterways Journal*, November 27, 1937.

[85] *Engineering News-Record*, April 7, 1937.

J. D. GALLOWAY,[86] M. AM. SOC. C. E. (by letter).—Although it would be possible to bring additional facts to support the data given in the able papers of this Symposium, it is believed that sufficient information is included in the four papers to enable conclusions to be drawn. In the words of Col. Wilgus (see heading, "A Challenge") they "constitute a terrific arraignment of those who are intrusted by the people of the United States with the handling of their affairs." However, the question naturally arises, why has such a condition come about and who is responsible? Many uneconomic projects have been undertaken, money by the hundreds of millions of dollars has been expended, and economic conditions are as bad as, or worse than, before. What is wrong with the program? The writer believes that the underlying causes are inherent in the nature of such programs and will examine the subject from that standpoint.

Advance Planning.—This theory has a superficial appearance of merit and Mr. Fay has outlined the best aspects of the subject. The fundamental defect of such planning lies in the fact that it is impossible to determine in advance what the needs of the future will be, or to anticipate the changes that only a few years will bring about. A few examples will make this point clear.

In the early years of the Nineteenth Century, a system of canals was projected and partly built in the Eastern States. Politics, "log-rolling," and much dishonesty characterized the work. Then railroads were invented and practically the entire system of canals was abandoned. The canals were a complete loss and the one remaining in use—the Erie—has been an excellent example of the losses resulting from Government in business. Of what value would have been a plan of canals over the country, when in a few years the entire system as built was abandoned? The writer has seen, in Indiana, remains of one of these canals that never even contained water.

The railroads of the country are another example. Fifty years ago they were the principal means of transport, and branch lines were built all over the land. The automobile was invented and in the past few years one of the jobs of the engineers of railroads has been the tearing out of abandoned branch lines. Of all the railroads, the interurban lines, generally operated by electric power, furnish an example of the type largely rendered obsolete by the automobile.

Modern highways furnish another example of the inability of engineering works to last. Due to the rapid development of automobile traffic, roads that were built as late as five years ago (1933, say) are now inadequate. An able engineer of the California State Highway Commission recently stated that an expenditure of at least $100 000 000 was required to make over roads built in the past few years.

Examples of this phase of the subject could be cited without number. It is a matter of common knowledge among engineers that change is the order of Nature and that what is built to-day will be found inadequate tomorrow. It is the price paid for progress. When Americans are satisfied with the works that their fathers built, the nation will have reached a state of stagnation that the writer, for one, does not desire to contemplate.

---

[86] Cons. Engr., San Francisco, Calif.

It will be contended by the advocates of advanced planning that general plans only should be laid out by the planners of to-day. The answer to this contention is that the men of tomorrow will not follow the plans made to-day. In any single piece of work, plans made by one set of men are usually ignored by their successors. The writer has in mind electric transmission lines in California. Lines built under one set of conditions become obsolete by changes in voltage, changes in the location of load center, and various other factors. The amalgamation of systems has altered the entire program. As long as growth continues, the changes that come about preclude any advance planning that would be of value in an emergency.

The most important factor in the case of advanced planning is that the best of plans will not be followed because the decision to say what program shall be followed in the assumed emergency does not rest with engineers. That decision is made by politicians. The United States has been governed in the past by politicians, is now in their hands, and as long as human nature remains as it is, the country will be governed by politicians. It matters little by what label they are designated, they run true to form. The Columbia River Basin is an excellent illustration of this fact. In reality, advanced plans had been made on that large river. For eight years prior to 1933 the river was made the subject of studies and reports and they were of the general tenor that economic development was not feasible at the present time. The entire river was covered. What was the result of all this study? The politicians gave into the hands of the President enormous sums of money to be expended at will and immediately became active to divert as much of the money as possible to the regions they represented. That was the determining factor in causing the adoption of Bonneville and Grand Coulee. All the advance planning availed as nothing against the chances to obtain slices of "pork."

Electric Power.—Closely connected with such decisions as are mentioned is the plan of the present Administration to place the National Government in the business of developing and selling electric energy. Whenever a dam of any size is projected, it becomes (except in special cases) an economic necessity to make the energy from the falling water available for human use. As a rule the energy in the form of electricity is a by-product of the development. However, in the cases mentioned in the Symposium and in another project on the Tennessee River, power has become the main objective of the installation. The President has stated in no uncertain terms that four projects in different sections of the country were being built as "yardsticks" to determine the cost of power. In addition, funds have been, and are being, donated by the National Treasury to various municipalities for the purpose of installing municipal plants that will drive privately owned plants out of business. At first, the sums advanced were 30% of the cost of the works, which sum was later increased to 45 per cent. In addition, the National Government purchased, or will purchase, the securities of the municipality. The result is an outright gift or subsidy offered by the Government for the purpose of wrecking the private industry and driving the owners out of business.

The same effect is produced by the construction of power plants at the various dams recently completed or nearing completion. In complete disregard as to whether there is a market for the power, expensive hydro-electric installations have been made. This is especially true in the Tennessee Valley where the numerous dams serve practically no purpose except as units in a power development. Some benefit will accrue in flood control but the operation of the system will determine the extent to which the reservoirs will be used for the latter purpose. There is an inherent opposition between the requirements for flood control and those of power generation. Flood control demands that reservoirs be largely or wholly emptied in anticipation of a possible flood. Power demands that the reservoirs be kept full so that a maximum fall of the water be obtained. It may be claimed that flood-control space is left in the upper part of the reservoir, but this again emphasizes the fact that power development is the major element in the project.

There is no deeper seated economic fallacy embedded in the public mind than that power costs as developed by private companies are excessively high. The corollary follows that in every power development there is an unlimited source of revenue, which will carry the burden of all the charges on any project, however lacking in merit it may be. Demagogic newspaper writers, and politicians, have "harped" upon the subject until the public has been completely bewildered by their claims. The development of systems of power generation and distribution either from fuel or by water, in the past fifty years, has had an effect upon modern life in America second in benefits only to the great transportation systems. A cheap source of energy that could be distributed in large or small quantities to all parts of the land has been brought into being by the American genius for invention and for organization. The power thus placed at the service of every one can only be measured by that of billions of men.

The great enterprises have been developed by private initiative operating under the laws of the country. There are numerous instances where some of the enterprises have been misused, and corporation piled on top of corporation, for which the public has been asked to pay. No engineer should defend such practices and few do. On the other hand, there are many States where governmental supervision has prevented such practices and where, as in California, an able commission has worked with the power corporations, to protect the public and also the corporations. As a whole, the power corporations have acted wisely and have reduced rates in accordance with increased business and increased efficiency of larger systems.

As, throughout the country, power systems generally extend over two or more States, it becomes the function of the National Government to provide the necessary regulation. That is the proper function of Government. On the contrary, it is not the function of Government to use its power in building power plants and by use of Federal subsidies, drive the private corporation out of business. There was no need for any "yardsticks" to determine the cost of electric energy. One honest engineer and one honest accountant could determine this cost at any location.

In the Pacific Northwest, where the Bonneville and Grand Coulee power developments are situated, the private and public plants already in existence have brought about a per capita use of electric energy greater than elsewhere in the country. The existing systems have been built to supply immediate needs and are capable of extensions which can supply all the electric energy now required or that may be needed in the future. The Government plants were unnecessary. There has recently appeared[87] a statement that at Bonneville the Government investment on June 30, 1938, amounted to $53 188 800 and that power would be charged with 32.5% of this sum. When the project is completed, the estimated cost will be $74 144 600, of which power will be charged 57%, or $42 191 175. The remainder of the costs (two-thirds in one case and nearly one-half in the other) is charged to navigation. It is with such juggling of costs that the "yardstick" will determine the costs of power. It will be noted that the 1934 estimate of $31 250 000 for this project, stated by Professor Riggs as $51 000 000 in 1936 (see "Significance of Contingent Expense"), has now (1938) grown to an ultimate of $74 144 600.

He also states (see "Power in the Northwest") that the Grand Coulee project now has an estimated cost of $437 000 000. There will be water to irrigate about 1 000 000 acres of land. The experience with the Reclamation Service projects, with few exceptions, shows that farmers cannot, and will not, pay the costs of such projects. They must compete with other lands not subject to the handicap of costly irrigation works and, furthermore, there is a widespread opinion that the Government should furnish the land and water free. The result is that no political management can make them pay. The favorite method has been to write off large sections of the cost of the project, to reduce the interest rates, and to extend the time of payment to a date far in the future. In California, irrigation districts having debts ranging from $15 to $50 per acre have gone insolvent because the farmers could not, or would not, pay their taxes. It is idle to expect that farmers under the Grand Coulee project will act otherwise, especially when Government gifts of all kind are being scattered broadcast. As a possible source of revenue to meet the charges on the Grand Coulee project, the farm lands may be dismissed from consideration. It is doubtful whether the lands could stand the cost of the required canal system. If any revenue is obtained, it will be in the distant future as the country is relatively undeveloped and now amply supplied with power.

Tendencies of Government.—It is recognized that there is a widespread belief throughout the United States in the principles of socialism, the fundamental basis of which is that all means of production should be owned and operated by Government. Parallel to this idea is the one that private ownership of property is an evil and Government should extinguish private rights by confiscation. Since the present Administration came into power it is the belief of the writer that a consistent course has been pursued by the Administration tending to destroy private property and private initiative. The most violent assault has been made upon the various power companies. Some of the means to this end are the several projects discussed in the papers of this Symposium. By apportioning a large proportion of the cost to such items as flood control or navigation, the power plant costs are reduced far below what they should be. This arrangement, together with outright gifts to municipalities written off by the Federal Treasury, may produce low-cost power, but as a measure of the correct costs of electric energy, the so-called "yardsticks" are designedly incorrect and without value as such. In the event that the policy of State socialism is made permanent, it would seem advisable to have the correct costs of any project determined, and not have the projects undertaken with the expressed purpose of altering the true costs by subsidies, direct or indirect, from the National Treasury.

---

[87] *Western Construction News*, March, 1938.

The most glaring examples of uneconomic power projects among those cited in the Symposium, is Passamaquoddy. In this case there was lacking the usual excuse of navigation, flood control, or irrigation. All the costs, if properly made in an honest system of accounting, would have had to be charged to the project. The fallacy that energy under modern conditions of demand can be obtained from the varying systems of tides was also present. Hence, a fuel power plant was required of equal capacity to the tidal power plant. The fact that the location was such that there was practically no market for the energy made the entire project a monumental failure from the beginning. However, the politicians at Washington succeeded in spending several millions of money before it fell of its own weight.

In the case of the Wilson Dam and power project, started during the World War, there is another example of unwise Government planning and execution. The country was engaged in a desperate war that required all its energies; yet some one of the politicians secured money from the Treasury to begin the Wilson Dam on the Tennessee River, the power from the plant to be used during the war for the manufacture of nitrates. Years after the war ended, work on the dam was still going forward. When the project was started it was recognized that on account of the variable flow of the river, a steam plant of a capacity about equal to the water-power plant was required, and it was built. It was merely another example of the governmental inaptitude and mismanagement in an emergency. To any one except a politician, it should have been apparent that in a time of a great war, to start a dam and hydroelectric power plant that could not be completed, that could not function, and that required a steam plant of practically equal capacity, was opposed to all ideas of the right thing to do; yet tens of millions of dollars were poured into the project that was obsolete from the start as a producer of nitrates for war purposes.

Opposed to the prevailing tendency toward socialism, there is the individualism of the past. Under whatever term of collectivism it may appear; socialism, communism, Government or municipal ownership, the present tendency is in direct and irreconcilable conflict with the individualism that has built the nation. It is admitted that all over the world at the present time, the doctrine of collectivism is in the ascendency. The moves of the present Administration at Washington are in line with the world tendency. The glaring examples of the adoption by Government of unsound, costly, and uneconomic projects, as set forth in the Symposium, merely express the retrogression into which this country is sliding. In the past, in spite of obvious errors, individualism and personal liberty have accomplished the greatest good for the human race. Compared to the blundering and hampering action of Government, the contrast is a vivid one; and yet, with the other nations of the world, the United States has parted from the system that has made it great, and with the others, is imitating the actions of a certain group of animals of old, which, possessed of devils, rushed down a steep place into the sea. The country is in danger and, in the words of Professor Riggs (see "Conclusions"), "engineers will fail in their duty if they keep silence."

E. S. MARTIN,[88] ASSOC. M. AM. SOC. C. E. (by letter).—This Symposium directed to the economic phase of the recently enlarged Federal activity in public works plainly pertains to the exigent character of this activity, and to the competence and propriety of Government in business. The abrupt cessation of the flow of investment funds into private works following 1930 forced the Government unpreparedly into the breach or, failing that, forced a complete moratorium upon the accumulation of investment funds. Professor Riggs' intimation that, as with the Panama Canal, Congress should have deliberated for three years before taking action on the great projects now under way, seems, to the writer, without force in the circumstances. It is certainly a debatable point that Congress should decide engineering questions in any circumstances. It is for Congress to consider and determine the sum, time, and purpose, but not generally to consider and determine technical details which its members are not usually trained to comprehend. This point is the origin and strength of the manager type of municipal government.

The economic aspects of any undertaking mean the trading relation of the undertaking to its economic environment. Everything in the business world is a link in a chain. To study the link alone and to presage how and which way it will jerk the chain along is somewhat bizarre. The condition of the chain demands consideration in determining the safety and service of the link. The writer is offering some considerations herein which the proponents of this Symposium have neglected regarding the will of the people to use new works or even those they have. He pleads that the authors take entirely too narrow a view of the problem. They view public works from the banker's and the investor's standpoint; whereas the purpose of this activity is to use some of the available capacity for service, otherwise idle, to serve the nation, and thereby to command service in return—in the language of the street, to make a living.

Professor Riggs again states (see heading, "Counting the Cost"), "the same sound business principles should control the selection of public construction projects which are to render a service that the public must pay for as would prevail in the case of a successful private undertaking of the same kind." The writer denies the very essence of this statement; public works and public finance are fundamentally different from private works and private finance. Private works are for the purpose of "making money" out of the public presumably by serving it, whereas public works are for use—for service only. The private investor often—but not always—aims to liquidate his investment; but there is no reason whatever for public works to be self-liquidating and there is no need for them to be financed by bonds; in fact, it is a crime against the public to do so. The Government is the one economic entity that has complete control of its income; it can balance its budget without injury to any one in war or peace.

---

[88] Secy.-Treas., James A. Wickett, Ltd., Toronto, Ont., Canada.

About 150 yr ago, pioneers migrated from the Atlantic Coast into the wilderness of Western New York and settled and developed that district. They did not prepare a prospectus to show (an investor) that the roads and works they built would pay or be self-liquidating. They were the investors and the users. Making a profession of investing, separate from enterprise, from material capital in modern finance, is not healthy. Mr. Henry Ford has taken pains that that did not happen to him; the same is true of thousands of other firms and of much of agriculture. From the ethical standpoint public works, by and for the public, should be free from private investors; that is, it should be paid for when built. The investor's field is private enterprise attended with risk, where invention and enterprise are essential—a field not suited to Government management.

In so far as this Symposium contributes to prevent waste of labor and material on developments that would be of no service, or of but little service, to Man, it is constructive and meritorious. One must bear in mind that with private enterprise as well as with Government managed enterprise the public provides the labor and materials and the money, too, through its patronage. Money is never consumed or wasted or saved or made. It is only the catalytic agent of trade; so that misapplication of effort is equally a public loss in either type of enterprise; in fact, the only difference between public and private enterprise is the question of who provides the management and gets the income, if any. When Government management excels private management in vision, enterprise, efficiency, and integrity, it will not take long to displace it. It is evident that Government enterprise is rapidly displacing private enterprise quite generally throughout the world, largely alas, because of the demoralization of private enterprise—more precisely, private investment. Professor Mead's reference to Canadian "fiascos" is not a happy one for his contention. Canadian trials at public management are uniformly outstanding successes; it is rather some private promotions in Canada, as in the United States, that are not so aromatic. Although the Canadian Pacific Railway was capably managed, the constituent private railways now forming the Canadian National Railway were in such bad physical and financial condition in 1915 as to threaten the solvency of Canadian banks and, possibly, the nation. Canada assumed and carries this indebtedness (which continues to grow), but the railway management is remarkably improved and compares with the best of American railroads. The same is true of the Toronto Transportation Commission and the provincial telephone systems in the West. The Ontario Hydro-Electric Commission outdoes, by a wide margin, the accomplishments of private systems of the United States. The writer has resided in Toronto for eighteen years following eight in New York, N. Y., and can warn his fellow members in "The States" not to refer to Canada to support an aversion to public ownership. The 8 cents to 10 cents per kw-hr that he paid in New York for domestic current as against the 1 to 1.5 cents in Toronto indicates the extent to which the consumer serves the investor in New York instead of the investor serving the consumer—which is his reason for being.

Now, the very extent, in area and time, of the Tennessee Valley development is such that no private enterprise could undertake this work in order to "make money"; nor could it be tolerated in any event; and, likewise the Columbia River projects. It is impossible for one now living to establish beyond question the tolerably exact value to Man of this kind of development, which depends for its use upon continued development in many directions. Such development is similar to that of the settlement of new domain; it cannot be reduced to a simple financial statement. From the writer's viewpoint, these are very promising, brilliant conceptions, as sure as most human undertakings. Some of the other projects, like the Passamaquoddy, do not offer the same promise, at least, they have not been shown to the writer's satisfaction to do so. The economist and the engineer must not overlook the inevitable risks always attending any enterprise; no one can see the future with perfect vision.

Public work has its pitfalls, as does private work. The selfish local interest which seeks public expenditures that it may benefit from it, whether or not the public does, has its counterpart in the investment broker who markets securities without conscientious solicitude for their soundness, or which do not represent equivalent increase in real material wealth. Mr. G. C. McDonald has stated[89] that total public debts in Canada increased about $1 800 000 000 during the six years, 1932 to 1938, with little or no increase of material wealth. The purpose of money savings and investment is to put and keep people at work creating fixed wealth; turning from this duty is exactly what causes public and private deficits and unemployment. There has been a forced attempt by the Government to discharge this duty in part.

The purpose of public and private improvements is to serve Man; in short to maintain and to raise standards of living, now or in the future. If the people do not live more fully these works are not used; and, conversely, if the nation's capacity for service is not employed, it is because its people are not spending their money. How secure, and how promising can any development be as long as the people of several rich nations decide deliberately not to spend (use) their money? Economics was formerly called Political Economy, and so it is.

K. BERT HIRASHIMA,[90] ESQ. (by letter).—The papers of this Symposium should prove of great value to all engineers whether or not they are engaged in planning work. The papers by Messrs Riggs, Mead, and Wilgus reveal some of the colossal mistakes that have resulted from hasty uneconomic planning. Through careful advance planning, it is to be hoped that past errors will not be repeated in the future.

One of the principal objects of long-range advance planning is to relieve (at least to some extent) the large volume of unemployment resulting from the fluctuations in the business cycle; but, as Mr. Fay states "a controlled public works policy should not be looked upon as a means of relieving, directly, unemployment among workers outside the construction industry by giving them employment on construction projects." To do so would only tend to upset the normal relation between the number of workers engaged in the construction industry and the number of workers engaged in other activities. The resulting unbalance may eventually prove to be as great a problem as the original one of unemployment when, with the return of better times, public works projects are "tapered off." Public works expenditures, therefore, should not be regarded as a panacea but as a kind of balance wheel to regulate the activities of one phase of the national economic picture, namely, the construction and allied industries.

---

[89] "The Plight of the Taxpayer," by George C. McDonald, *Canadian Business*, Vol. 11, No. 2 (February, 1938), pp. 16–18.

[90] Asst. Highway Planning Engr., Territorial Highway Dept., Honolulu, Hawaii.

As to the financing of a long-range public works program, Mr. Fay mentions two methods: The accumulation of a reserve fund during boom periods, and long-term or short-term borrowing.

The question of just how the reserve fund should be accumulated is a difficult one. In the accumulation of any reserve fund, the assumption is made that assets can be liquidated at approximately the cost price; but the greatest demands upon a public works reserve fund will fall during periods of depression when security prices are at their lowest.

The issuance of bonds for unemployment relief is unjust in that it is nothing less than asking future generations to pay for present unemployment, unless the relief projects are of a self-liquidating character. When the bonds mature, money in the form of taxes must be diverted from the channels of trade to pay for them. This means that some worker, somewhere, is deprived of a chance to work.

In boom times, money is freely exchanged for goods and services; it is then performing its legitimate function as a medium of exchange. During periods of depression, the demand for money is greater than the demand for goods. Capital, unable to earn a profit and fearing taxation, "goes into hiding" in the form of bank deposits or tax-free bonds.

The fact that Government bonds can be sold to finance unemployment relief proves that there is an abundance of idle funds—money that has ceased to perform its function as a medium of exchange. It is not asking too much that such funds be taxed accordingly. Any long-range planning, therefore, should take these factors into account; otherwise, the issuance of public works unemployment bonds will only provide opportunity for additional capital to be removed from circulation. In this connection, President Roosevelt's suggestion that future issues of Government bonds be taxed, is a step in the right direction.

Lastly, the problem of public works planning is not a static but a dynamic one; that is, the factors involved are changing continuously.

LOUIS E. AYRES,[91] M. AM. SOC. C. E. (by letter).—It is unfortunate that no definite pronouncement, allocating expenditures for power purposes, has ever been made by the Tennessee Valley Authority (TVA). Lacking such pronouncement, Professor Mead calls attention to certain estimates in "testimony before the House Appropriations Committee"[11] (see heading, "Government Interference as a Permanent Policy: Power") in 1936 wherein the "estimated annual power expense" of $12 191 000 was arrived at by taking 9% of $135 450 000, the investment in "power houses and power facilities" only. Obviously, such an assumption will not generally be accepted as a basis for determining a power production "yardstick."

---

[91] Cons. Engr. (Ayres, Lewis, Norris & May), Ann Arbor, Mich.

[11] First Deficiency Appropriations Bill, March, 1936.

An engineer would normally analyze the basic data in quite a different manner. The usual method to obtain the investment base which may be supported by a given gross income is to divide the gross income by the percentage of annual charges. Those acquainted with water power costs will generally agree that a total of 10%, with interest at 6%, is usually adequate for annual charges in the case of large, privately owned water powers; and if interest is assumed at 3.5%, the annual charges become about 7.5 per cent. In the case, however, of such projects as those constructed by TVA, with possibly as much as one-half the project cost invested in reservoirs (including highway and railroad relocations, which involve very little maintenance and operation and no depreciation), one may use a lower percentage for annual charges than in projects involving relatively larger proportions of the investment in structures and equipment. A value as low as 6.5% was used by H. K. Barrows, M. Am. Soc. C. E.,[92] in computing fixed charges on Boulder Dam, Bonneville, Grand Coulee, and the TVA projects. In the writer's opinion 7% is sufficient, under TVA conditions, to cover all charges, including interest, depreciation, taxes (as assessed under private ownership), insurance, operation, and maintenance. Furthermore, if the "estimated gross annual wholesale power revenue" of $23 120 000 is divided by 0.07, the investment base, or the production "yardstick" of TVA becomes $330 000 000.

However, Professor Mead questions the TVA estimates of annual income, first as regards the amount of output that may be utilized, and second as regards the average unit revenue that may be obtained therefrom, based on the rate schedules now in effect.

As to saleable output, Professor Mead states (see heading, "Government Interference as a Permanent Policy: Power") that the "estimated output is based on continuous efficiencies of more than 80%," and infers that "other losses due to plant use, transmission losses, transformer losses, and losses due to regulation for navigation and flood prevention" have been overlooked. This is not in accordance with the writer's understanding. In the TVA report to Congress, March, 1936, entitled "The Unified Development of the Tennessee River System," the estimate of 660 000 kw of continuous capacity was qualified by the sentence: "By continuous power is meant the dependable power which would be available 24 hours of the day and 365 days of the year after suitable deductions for expected and unavoidable water and energy losses." The writer understands that these deductions included restrictive assumptions as to flood control, allowances for navigation, evaporation, leakage, and seepage, and a final utilization factor of 90 per cent. In effect, all deductions, together with normal allowances for unit efficiencies, approximated an assumption of utilization at the switchboard of less than two-thirds of the theoretical power of all firm water, which is a somewhat more conservative basis than Professor Mead's 80% of 80% or 64%, including transformer and transmission losses.

---

[92] *Proceedings*, Am. Soc. C. E., April, 1938, p. 698.

As to average annual unit revenue, Professor Mead presents, incompletely, the TVA wholesale rate schedule and concludes: "From these rates it is evident that the annual returns, if and when markets are found for the entire output, cannot average as much as 3 mills per kw-hr." Such a conclusion can hardly be drawn, from the rate schedule considered, as the demand charge alone of 90 cents per kw per month amounts to 2.46 mills per kw-hr, at 50% load factor, and the lowest step in the energy charge is 2.0 mills per kw-hr. Hence, wholesale power, purchased in large blocks under this schedule, would cost more than 4.46 mills per kw-hr, if a load factor of 50% obtains, as assumed by Professor Mead. One must assume 100% load factor to obtain a value approximating 3 mills, and then only because energy purchased in any month in excess of 360 times the demand is subject to a reduction of 0.5 mill per kw-hr. Also, energy purchased at the Authority's switchboard is subject to a further reduction of 10 per cent. These conditions of the schedule could account for the press dispatches of sales to "a chemical company," referred to by Professor Mead, of "firm power" at 2.74 mills per kw-hr. However, no one will assume that any considerable portion of TVA output will be sold at 100% load factor. If it is used to the best advantage eventually much of the output will be produced at 40% load factor or less, and will return a unit income of 5 mills or more. That firm power can be produced at 40% load factor or less may be judged from the fact that the total installed machinery contemplated is 1 922 000 kw, or slightly less than three times the estimated 660 000 kw of 24-hr firm power. Hence, it would seem that the TVA estimate based on 4 mills per kw-hr for firm output is conservative, having in mind the best ultimate use of this water power.

In addition to the firm output, however, there will be a considerable production of secondary power. Professor Mead is "aware that contracts have already been made to supply a considerable quantity of such power." Why should the income from secondary power be neglected? It would not be overlooked in a private undertaking. Professor Mead refers to press dispatches quoting sales of "12 000 kw of 'run-of-river power,' at 2.27 mills per kw-hr." Although there seem to be no published estimates of the amount of this secondary power, it would probably be not less than 2 000 000 000 kw-hr annually and would have a potential value of from 1 mill to 2 mills per kw-hr.

Assuming an average return of 5 mills per kw-hr for firm power and 1.5 mills per kw-hr for secondary power, the gross annual income amounts to about $32 000 000, which sum, capitalized at 7%, results in an investment base of $457 000 000; or, assuming 4 mills per kw-hr only for firm power and 1 mill only for secondary power, the annual income is computed to be about $25 000 000 and the investment base, $360 000 000, which is still in excess of Professor Mead's estimate of $353 150 000 as the proper "total cost of power installation."

An important hurdle in the path of any general agreement as to a proper power production "yardstick" is the allocation of total expenditures to the several purposes of navigation, flood control, and power. In determining his allowance for navigation, Professor Mead refers to the Army Engineers' estimate[15] of $74 709 000 for "navigation works with low locks and dams," agrees "that the higher dams will possibly improve navigation facilities," and concludes that "say, $90 000 000 for this purpose might be warranted." More recent estimates of the cost of a 9-ft channel, from Paducah, Ky., to Knoxville, Tenn., to the same standards as those used on the Upper Mississippi and Ohio Rivers, are much higher than the older estimates. In January, 1938, C. T. Barker, Assoc. M. Am. Soc. C. E., Head of the Navigation Section of TVA, testified in the constitutionality case in Chattanooga, Tenn., that to secure a navigable channel meeting present standards and requirements, by means of a series of low dams, would cost $144 072 700. If one assumes, therefore, that navigation may properly be charged with an amount substantially equal to what it would cost to provide the equivalent facilities by works constructed solely for that purpose, Professor Mead's allowance should be increased by at least 60 per cent. Obviously, the low-dam scheme would involve greater operating, maintenance, and dredging costs than the high-dam scheme which is being built, and would be less desirable for this and other reasons.

In the matter of flood protection, it may be recalled that the Army Engineers estimated that about $45 000 000 would prevent the maximum possible damage on the Tennessee River. Professor Mead allows $36 000 000 only, although he adds that "indirect damages might warrant some additional expense." In the "Comprehensive Report on Reservoirs in Mississippi River Basin,"[93] there is a list of 21 reservoir sites in the Tennessee Valley which would provide 10 188 100 acre-ft of flood storage at a cost of $167 282 000, or $16.40 per acre-ft. This is part of a list of 81 reservoirs in the Ohio Valley with a total storage capacity of 25 285 400 acre-ft at $20.40 per acre-ft; part of a total of 106 reservoirs up stream from Cairo, Ill., with 52 853 400 acre-ft, at $15.70 per acre-ft; and part of a grand total of 151 reservoirs, above the latitude of Red River Landing, La., with a total capacity of 98 677 900 acre-ft, at $11.40 per acre-ft. If one then assumes a value as low as $11.40 per acre-ft for the approximately 9 000 000 acre-ft of flood-control storage, provided by the TVA projects, the total is about $100 000 000.

Professor Mead quotes Mr. Morgan as testifying[16] in 1936 that the "value of the flood protection feature will be worth $100 000 000 to flood protection on the Lower Mississippi River." This value was based on the cost of raising Mississippi levees 3 to 4 ft, or the estimated lowering effect of TVA dams on a maximum Mississippi River flood. Carl A. Bock, M. Am. Soc. C. E., Assistant Chief Engineer, TVA, has stated[94] that the reservoir value of Gilbertsville alone "in protection to lands and improvements in the upper portion of the alluvial valley of the Mississippi River has been conservatively estimated to be approximately $90 000 000." Professor Mead, however, discards these benefits as problematical and outside the "primary objective of TVA," although under the TVA Act, as amended, the Authority is empowered "to construct such dams and reservoirs as * * * will best serve to * * * control destructive flood waters in the Tennessee and Mississippi River drainage basins."

---

[93] H. R. Doc. No. 259, 74th Cong., 1st Session, p. 46.

[94] *Engineering News-Record*, April 7, 1938, p. 500.

On the basis of the foregoing assumptions, one might evaluate the multiple-purpose project as follows:

Purpose		Total	Percentage of total
Power		$360 000 000	56.2
Navigation		144 000 000	22.5
Flood control		136 000 000	21.3
Tennessee Valley (according to Professor Mead)	$36 000 000	....	....
Mississippi Valley (according to Mr. Morgan)	100 000 000	....	....
Total		$640 000 000	100.0

The increase in the size of the Gilbertsville and Fontana Dams, since 1936, and added generating units at several plants have raised the estimated total cost of the eleven projects, exclusive of transmission lines, according to testimony before the House Appropriations Committee (Independent Offices Appropriations Bill for 1939), to about $505 000 000; and, if 56.2% of this sum is chargeable to power production, the power "yardstick" becomes about $285 000 000. In the writer's opinion, a proper allocation to power, exclusive of transmission line costs, should not exceed $300 000 000. Such an allocation would be $60 000 000 less than the investment base, indicated herein, upon which the gross estimated income, from a fully developed market, would pay all charges; and, hence, $60 000 000 might be assumed as available for interest deficits over a period of market development. In other words, on this basis, if the market could be fully developed by, say, 1950, the projects would pay all charges on a fair power "yardstick," assuming 7% for annual charges and the sale of all firm output at 4 mills and all secondary output at 1 mill per kw-hr.

Professor Mead states that: "Steam power can certainly be generated in the Tennessee Valley for not to exceed 4 mills per kw-hr." If this statement is premised on a load factor of 50%, as one may infer from the context, it is believed by the writer to be too low if all costs are considered. Units have been added to plants where the incremental cost was 4 mills per kw-hr at 50% load factor, and plants containing one or two large units, without reserve, may be as low as 4 mills per kw-hr; but a more representative cost of steam power in this area, with all charges considered and adequate reserve provided, can be shown to be 5 mills or more for energy at 50% load factor, construction costs at $85 per kw of installed capacity, and coal at 12 cents per million Btu.

Thus, the engineer may conclude that the Tennessee Valley projects are sound, based on the usual analyses. The construction work done is certainly excellent, as one might expect from the competent engineering personnel that has designed and constructed the projects. The cost of producing power is certainly comparable with, if not less than by, steam substitution; and, the value of the energy will be enhanced as it is utilized in a more fully developed market. The principal economic difficulty involved at present would appear to be one of market, and that in turn is largely dependent upon the settlement of a controversy. One may not condemn the TVA on the basis of switchboard costs. The real TVA controversy is not at the switchboard but at the consumer's meter. One deals in mills at the switchboard, but in cents at the consumer's meter. Most of the "yardstick" is beyond the switchboard. It would seem to be a safe assumption that if the TVA output were allowed to be sold at the switchboard to existing utilities, on the basis of existing TVA rate schedules and without "strings attached" to its use, substantially the entire output would soon be disposed of, to the mutual advantage of both the Government and the purchasers. However, TVA has not seen fit to stop at the switchboard. It insists on lower rates to the ultimate consumers, and its policy in this regard is the real cause of all the acrimonious controversy.

JOHN H. MEURSINGE,[95] ASSOC. M. AM. SOC. C. E. (by letter).—For a period of 300 000 yr human beings have tried to make a living by exploiting the natural resources of the earth to the extent that such exploitation did not tax the human intelligence beyond capacity. While this knowledge was growing in power, Man learned to develop new resources; but it was not until rather recently that he awakened to the fact that each newly developed contrivance meant another change in the social organization in which he happened to live.

Man has paid dearly for his insufficient knowledge by disastrous warfares and expensive social experiments. It was by the method of trial and error, and by reshaping his previous efforts that he was carried along the road of progress. The public works policy of the present Administration, for instance, adds another adventure to the long list of hazardous occurrences which mankind has encountered during his eternal journey. This policy will reflect upon the society of to-day.

Although this may seem very important to contemporaries, nevertheless the present public works policy should be considered as nothing but an infinitely small link in an inexhaustible chain of events which has carried technics through five phases (there will be more) to its present peak in the United States (see Table 9).

Phase 1.—According to the best available knowledge, Man's first ancestors lived in the tropics (the Java Man). Seeds (grains), roots (vegetables) and fruits were his food. Grasses, leaves, and leaf wood made up the materials for construction. The social organization consisted of "individuals." The women took care of the children. This type of social organization is rarely found any more. Even in the most remote parts of the jungle, newer phases have shown their reflection upon this kind of society.

Phase 2.—The hunter's period comes next. Man's technical ingenuity had a tremendous influence upon the society in which he lived. He invented tools with which to kill, and the social result was marriage, or the establishment of the "family."[96] To his vegetarian diet the jungle man began to add the meat of the game. Soon he was not confined to the tropics; Man migrated on to the plains where meat, quite often, became his exclusive food. Fire kept him warm and manure, skins, and bones were added to the construction materials. The women were physically unfit for the hunt, and, consequently, they became dependent upon the males. Technics had accomplished its first change in society.

---

[95] Huntington Park, Calif.

TABLE 9.—THE RELATION BETWEEN THE EVOLUTION OF TECHNICS AND OF SOCIETY

Phase	Power resource	Material resource†	Social unit and center of production and distribution	Typical occupation	Civilizations
1	Seeds, roots, and fruits	Grasses, leaves, and leaf wood	Individual	Jungle man	Ancient tropical cultures
2	Men, animals, and fire	Manure, skin, and bones	Family	Hunter	Indians of North American plains; Magdaleniun cultures in Europe
3	Slaves, agricultural products, and domestic animals	Clays, bricks, and natural stone	City	Farmer	Aztecs, Mayas, Incas; Chinese, Babylonians, Assyrians, Arabs; Egyptians, Phœnicians; and, Greeks and Romans
4	Stone, water, and wind*	Cotton, fir wood, and glass	Nation	Business man	Portugal, Spain, Northern Italy, Holland, France, and England
5	Coal, oil, and natural gas*	Metals	World	Industrial worker	Austria, Germany, United States, and Russia

* Electricity is a power created from the resources of Phases 4 and 5.
† Material resources of Phase 6 are rubber, aluminum, and magnesium.

The Indians of the North American plains, and the Magdaleniun cultures which appeared in Europe about 25 000 yr ago are representatives of Phase 2.[97]

Phase 3.—Technical accomplishment kept pace with the ever-growing population. Improved technics made possible the exploitation of plants, animals, and slaves. The new materials—clay, brick, and natural stones—were used for roads, bridges, and houses. An entirely new type of society, which revolved about the farmer, came into existence. Specialization in farming and the instinct of self-preservation gave birth to the "city." Mankind had stopped roaming. The Aztecs, Mayas, and Incas in the Americas; the Chinese, Babylonians, Assyrians, and the Arabs in Asia; the Egyptians and Phoenicians, in Africa; Greeks and Romans in Europe, were the great civilizations of this era (5 000 B.C. to 1 000 A.D.).

Phase 4.—The next step in this evolutionary process was the exploitation of wind and water for power resources; cotton, fir wood, and glass for construction materials. Portugal, Spain, Northern Italy, with Florence and Venice, Holland, France, and England, which countries happened to have the resources of this phase, carried civilization to new peaks. This era has been named eotechnics by Lewis Mumford.[98] Technical accomplishments could prove another change in society; the city had grown into a "nation"; and, as all the countries of this phase had acquired colonies, a new type of occupation had arisen; the trader or business man was added to the jungle man, hunter, and farmer.

---

[96] "Kulturgeschichte der Menschheit in ihrem organischen Aufbau," by Julius Lippert, Verlag Ferdinand Enke, Stuttgart, 1886. Partly tr. by Peter Murdock, Assistant Professor of the Science of Society in Yale Univ., under the title, "The Evolution of Culture," Macmillan Co., New York, 1931.

[97] "The New Stone Age in Northern Europe," by John M. Tyler, N. Y., Charles Scribner's Sons, 1921.

Phase 5.—France and England had both shown the signs of a new phase. The underground resources were ready for extensive exploitation. A new type of technical complex, called paleotechnics by the late Professor Patrick Geddes, used coal, oil, and natural gas for power, zinc, copper, nickel, cobalt, iron, manganese, chromium, vanadium, and titanium for construction materials. Judging by contemporary developments, Austria, Germany, the United States, and Russia will make the most of these resources. Their technical accomplishments created the "industrial worker" as a new type of worker, and his international relations point to the entire world, instead of to the nation, as his social unit.

Technics developed Man from a jungle man into an industrial worker; it developed his individualism into internationalism. The relation between technics and social organization cannot be denied. Lewis Mumford[98] expresses this relation as follows:

> "While each of the phases roughly represents a period of human history, it is characterized even more significantly by the fact that it forms a technological complex. Each phase, that is, has its origin in certain definite regions and tends to employ certain special resources and raw material. Each phase has its specific means of utilizing and generating energy, and its special form of production. Finally, each phase brings into existence particular types of workers, trains them in particular ways, develops certain aptitudes and discourages others, and drains upon and further develops certain aspects of the social heritage."

Although each new phase has always strongly reflected upon the civilizations in existence, the old civilizations were never able to regain their positions as world powers by adopting the methods of the newcomers. Most interesting, however, is the fact that they always reluctantly adopted the new ways, and hence always hastened their own decline. Another interesting phenomenon is the fact that the process has been evolutionary. No sharp lines can be drawn between the phases as they penetrate each other.

The typical worker of each phase believes in the economics of his own phase only. The man of the jungle claims that it is uneconomical to be hampered by women and children in his forays; the hunter claims that it is uneconomical to build the city; the farmer objects to the national policies of taxing imports; and the business man cannot understand why the worker should spend a part of his wages on international causes.

The five phases have not only developed five different societies and five different occupations; they have developed five kinds of economics. Although eotechnics (Phase 4) developed the economics of investment, interests, and profits, the jungle man (Phase 1), the Eskimo (Phase 2), the farmer who wrings his entire living from the soil (Phase 3), and the industrial worker (Phase 5), the world over, are rather indifferent to the economics of dollars and cents.

---

[98] "Technics and Civilization," by Lewis Mumford, Harcourt, N. Y., 1934.

Here the conclusion may be drawn that these economics are limited to Phase 4. Economics is as much subject to the rules of evolution as anything else. Each of the authors of the Symposium overlooked this phenomenon.

The Symposium resembles the skillful work of a photographer. All the details of the subject have been shown with painstaking accuracy. The exposure has been well timed. Unfortunately, however, the camera has been placed so closely to the subject that only a limited field could be covered. It has been taken from the "eotechnical point" of view (Phase 4).

The science of economics is concerned with the production and distribution of the necessities of life. How has this been done since Man has been on earth? The jungle man searched the vicinity of his abode. The hunter could not leave his home for fear the fire might go out. Hence, the family assisted in production and distribution. In the next phase the specialization in farming made the city the center from which the goods produced were distributed. In the fourth and fifth phases, the city was replaced, respectively by the nation and the world.

The production and distribution center could not have grown in size so continually, had it not been for the aid of technics. Engineering accomplishments made possible better and faster production and transportation. Hence, engineering economics should embrace the problem of making "necessary" additions to the production and distribution system. These additions should keep pace with the evolutionary growth of the system.

Unfortunately, the science of the evolution of economics is still so much in its infancy, and it is looked upon with so much suspicion, that it is rather useless to discuss engineering economics until some kind of an idea has been formulated as to what kind of economics and technics Phases 5 and 6 will eventually create. Hence, it is impossible to say whether or not the present public works policy (addition to the production system) is economically warranted. Those who criticize and those who acclaim it are simply giving vent to their emotions. It behooves the engineer to approach this problem from a scientific angle only.

Conclusion.—The civilizations of each phase have been dominated by the workers created by that phase; but this does not mean that the occupations of the preceding phases had no place in their society. Their place was determined by the age of the phase to which they belonged.

To-day, for instance, in the United States the jungle man (Phase 1) and the hunter (Phase 2) have disappeared. The farmer (Phase 3), the business man (Phase 4), and the industrial worker (Phase 5) are still in existence, and, whereas the farmer's influence upon society is on the down grade, that of the industrial worker is on the up grade. The same can be said about the centers of production and distribution. The old evolutionary law is to-day as keenly felt as it was 300 000 yr ago.

During all this time the civil engineer has kept the road of progress in fairly good condition. Whereas the jungle man (Phase 1) was not in need of transportation, the hunter (Phase 2) needed trails; and the farmer (Phase 3) who traveled by wagon or on horseback, needed roads. The eotechnic (Phase 4) people who used sailing ships for hundreds of years needed the civil engineer to build and maintain canals and harbor works.

To-day, the paleotechnical (Phase 5) people are going forward in gasoline propelled engines, and the road of progress is in need of improvement. Grades and curves must be brought up to modern standards to eliminate obstructed views. Increased width should give ample room for the farmer (Phase 3), the business man (Phase 4), and the industrial worker (Phase 5) alike. Danger and speed-limit signs should keep the evolutionary traffic at a moderate speed; and swift justice should be dealt to those dangerous individuals who insist on driving in reverse "back to normal." They endanger the lives of millions of their fellow men.

If the civil engineer will build this "road" properly it will lead to a society in which the social rights of each worker are determined by the importance of the relative natural resources to society as a whole.

Samuel B. Folk,[99] Assoc. M. Am. Soc. C. E. (by letter).—In succinct manner Mr. Fay has shown the advantages of orderly planning. The next logical step is to note what can be planned. The Administration's budget, as released to newspapers on January 5, 1938, lists:

General Public Works:	
TVA	$ 46 000 000
Commerce	1 850 000
Interior	55 973 100
Justice	2 041 200
State	3 400 000
Treasury	58 107 000
Public Works:	
Highways	$104 640 100
Rivers and harbors	36 168 000
Rural electrification	39 514 800
Other public works	200 049 300
Total	$545 743 500

No amount of orderly planning of $600 000 000 will keep the pendulum of prosperity swinging when the total construction in the United States drops from $12 000 000 000 in 1928 to $4 000 000 000 in 1934 (see Table 1). However, it can help it keep a small oscillation, when the essential factor is to keep it from stopping entirely. Hence, engineers should analyze the types of public works that can be planned in an orderly manner and they should propose a program designed to help keep the wheels moving to elevate the standard of living. Among the numerous public works projects that (*a*) can be planned in advance; (*b*) can be at least partly liquidated; (*c*) will add to the well-being of the nation; (*d*) will reduce the cost of crime; and incidentally (*e*) will assist in returning the engineer to a respectable place in the mind of society—is public housing. Since this activity does not compete with services already offered by private corporations it is not in the category of some of the other projects mentioned in papers of this Symposium. Early in 1933 the idea that private initiative could satisfy all housing needs was abandoned. A small beginning has been made on sound principles, which the authors of these papers must surely endorse:[100]

---

[99] Associate Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

> "The PWA housing program produced fifty-one sound, workable projects which afforded a total of approximately 22 000 living units. Base rents averaging $5.65 per room per month had been established on 23 of them when the program was transferred to the United States Housing Authority. This figure was the 'shelter' rent and an additional charge of $1.82 per room per month provided heat, hot and cold water, electricity for lighting and cooking, or gas for cooking if that fuel was to be used. At these low figures, former slum dwellers obtained good shelter, ample light and air, modern equipment and generally salubrious surroundings.
>
> "The average income of the families in the PWA projects is low, and every family admitted was taken from substandard housing. In one of the Montgomery, Alabama, projects, the average income of tenants is $12.50 per week. In Techwood, Atlanta, it is $22.11 per week; in Atlantic City, $26.46, Miami, $19.15."

When it is realized that this has been done in spite of the advance in materials prices, high costs, and high taxes, it is even more remarkable. In reference to the general property tax on urban improvements, Harold M. Groves, Professor of Public Finance, at the University of Wisconsin, has remarked:[101] "It seems odd that we should have singled out for especially heavy taxation under the property tax, an interest which we now seek to subsidize as 'low-cost housing'."

Regarding the high prices, the U. S. Bureau of Labor Statistics gives the relative wholesale prices of important building materials cited in Table 10.[102]

TABLE 10.—RELATIVE WHOLESALE PRICES OF BUILDING MATERIALS (1926 EQUALS 100)

Average for year	Brick and tile	Cement	Lumber	Paint, etc.	Plumbing and heating	Structural steel	Other building materials	All building materials
1929	94.3	91.8	93.8	94.9	95.0	98.1	97.7	95.4
1932	77.3	77.2	58.5	71.7	66.8	80.9	79.5	71.4
1937	93.5	95.5	99.0	83.4	78.8	113.2	99.1	95.2

It will be observed that, although the national income in 1937 was only a little more than two-thirds of that in 1929, the prices of all building materials were almost exactly those of 1929 and land costs were still held at exorbitant values by real estate speculators who bought before the Government could get possession of the land for housing projects. These data are affirmed by reports[103] that construction costs are up 9% in 1938, as compared with 1937. Private initiative can do little against these odds to provide housing at the pocket-book level of the lowest quarter of the population. "No industrial organization is equipped to produce the kind and amount of houses we need, while conditions within our cities are such as to discourage rather than encourage industry in so equipping itself."[104]

[101] "What to Do About Taxes," *New Republic*, December 29, 1937.

[102] *Peoples Lobby Bulletin*, March, 1938.

To indicate further the complexity of the private building industry, a study of the Knickerbocker Village project in New York City accommodating about 1 600 "white collar" workers and their families, has been made.[105] The materials cost \$2 636 000; labor, \$2 020 000; overhead, \$1 561 000; and land, \$3 250 000. To reduce labor costs 25% (labor received an average of \$1.15 per hr), as has so often been suggested, would have reduced the cost 5% and would have reduced the rentals only 3.3 per cent. This does not indicate that any one factor is blameless, but that modern methods, reduction in land costs, materials, and overhead, Government subsidy, or outright Federal housing might be the best solution.

From these data it is observed that the engineer's attack on public works as a solution to prosperity must start much deeper than the Symposium indicates. Even after reducing the problem to fundamentals, pressure will be discovered from unexpected sources. Architecture is still very conservative, as it relates to public construction, and financial interests oppose any radical change of types of buildings, as may be noted in the following:[106]

> "When recently the mechanized industries, particularly in metal, entered the housing field with the production of 'Prefabricated Houses,' they were met by the resistance of property holders, especially of the banks, who hold mortgages on about 58% of 1933 value of all urban real estate, and who fear that an influx of cheap modern dwelling would subtract substantially from the market value of existing structures."

Professor Mead has mentioned the interference of Government in business (see "The Record of Government in Business") but has neglected the interference of business in Government. Much legislation is lobbied by trade associations that want, as John T. Flynn, the Economist, has stated:[107] "Less Government in business for me; more Government in business for the other fellow." All want tariffs, subsidies, and laws. Contrary to Professor Mead's opinion, Government in industry has not always been so unsatisfactory. In a brief discussion, data cannot be cited of the success of public water-works, electric plants, highways, bridges, and ferries. There are projects more extensive in scope and area, however, than any one State could undertake and expect success. On the other hand, to be fair, one should note that many private ventures are failures. The railroads have been built and maintained with constant subsidies from the Public Treasury. The story of the financing of the systems is not entirely creditable. Private initiative could not undertake a comprehensive policy of regional development of the Tennessee Valley. Even if it could, many think it is better to have it developed by Federal authority in order that the social shocks can be absorbed.

[107] Syndicated column in *The Columbus Citizen* and other newspapers, February 5, 1936.

The social effect may be as important as that of many past technical inventions. History has recorded the opposition to nearly every milestone in progress. Note the law sought to prevent the use of coaches in Hungary in 1523,[108] the opposition of the turnpike companies who profited by tolls, and the objections of canal owners to the railroads. The list reads like a catalog of inventions—air-brakes opposed; objections to electric locomotives on account of capital equipment loss, to subways, interurbans, and trucks. Steamships were opposed by the British Navy. The telegraph companies had a chance to buy the telephone, but chose to fight it. Bath-tubs were opposed, legislated against, and taxed. The newspapers fight the radio news. Just now History is writing the opposition to TVA, predicated on the idea that honest people have invested in public utility securities. Fate, however, is not cognizant of the honesty of men when new inventions cause obsolescence of old ideas and old methods or when financial jugglers out-manipulate the investor by pyramiding holding companies. Progress cannot be halted even if bankruptcy is in order for some industries. "In all previous depressions," states Professor Mead, "the responsibility for recovery has been met largely by the business interests of the country" (see "Government Function in Business Recessions and Recovery"). He should further note, as all business leaders did, that in all previous depressions there was not the large debt structure that burdened the country as in 1929, and that business beat a path to Washington demanding that Government "do something" about the sorry state of affairs. Previous depressions were ended when debts were written off, and agriculture and industry started anew to spend for consumptive products, including new inventions which employed a large amount of help. All efforts in this depression were in the direction of saving the debts and creating new ones, thus ear-marking nearly all income for interest. This is neither bankruptcy nor progress.

With his further statement that "The Administration has also urged the engineering schools to teach their students to consider not only the design and construction of engineering works but also to study and determine their ultimate effects on society" the writer, as an educator, agrees wholeheartedly. Most graduates leave college ignorant of the effect of science on culture, and new developments "hatch" so rapidly that the graduate never catches up, but remains saturated with the narrowness of his specialty. One required reading of the "Social Effects of Inventions" and "Resistances to the Adoption of Technological Innovations"[109] might open the doors to a wider knowledge of the effect of their own engineering work on society.

With regard to his opinion that "power development as an objective is not a legal function of the Federal Government" (see "Government Interference as a Permanent Policy: Power"), reference should be made to the Ashwander *v.*

[109] "Technological Trends and National Policy," Sections III and IV, National Resources Committee, June, 1937, pp. 24–66.

Tennessee Valley Authority case (56 U.S. 466) in 1936 when the Supreme Court held that, "the Wilson Dam and its power plant must be taken to have been constructed in the exercise of constitutional functions of the Federal Government." Further, in Tennessee Electric Power Co. *v.* Tennessee Valley Authority (Fed. Supp. 947 District Court Tennessee E.D.) the Court held:

> "The Court is of the opinion that the relative value of these various plans is immaterial, since it has been established that the TVA project is reasonably adapted to use for combined flood control, navigation, power, and national defense, and that in actual operation the creation of energy is subordinated to the needs of navigation and flood control. * * * The dams and their power equipment, both constructed, under construction, and authorized, must be taken to have been authorized, constructed and planned in the exercise of the constitutional functions of the Government. * * *"
>
> "While the Government, in selling property of the United States, performs many functions, that would be performed in the operation of a private business trading in similar property, inasmuch as the energy sold is created at dams lawfully erected within the Federal power, the Government in performing these functions is not entering into private business. It is merely using an appropriate method of disposing of its property. The Government may sell land belonging to the United States in competition with a real estate agency, carry parcels in competition with express companies, and manage and control its thousands of square miles of national parks even as a private company. The Government has an equal right to sell hydroelectric power, lawfully created, in competition with a private utility. * * * These complainants have no immunity from lawful competition, even if their business be curtailed or destroyed."

However, the essential problem is to develop a modern and progressive viewpoint by engineers, especially civil engineers, who by training and employment are more closely affiliated with public problems than others whose work is allied with large industries not so closely tuned to the common weal. The civil engineer ought to be the first to recognize that "control of power is a social as well as an engineering and economic problem."[110] This being true, perhaps some new methods of analyzing public projects must be devised. The price criteria set up by Mr. Morris L. Cooke might be used as a start. He suggests[111] that the primary principle underlying a national power policy, both as to wholesale and retail prices, should be service at the lowest reasonable cost to consumers, with the benefit of any favorable conditions attached to Federal ownership and operation. Factors involved in establishing the "lowest reasonable cost" are: (1) Rational allocation of the costs of multiple-purpose projects; (2) amortization of the allocated cost of construction during the life of the property; (3) interest; (4) taxes, as under the TVA, where a percentage of gross is paid to the States; (5) cost of maintenance; (6) cost of operation (administrative, commercial, technical); and (7), cost of direct promotion of more intensive use.

Quoting Mr. Cooke:

> "Exceptions to this governing principle, in the form of sale at less than cost as computed by conventional accounting methods, should be allowed only on

---

[110] Vice-Chairman Basil Manly, of the Federal Power Commission, quoted report of the National Resources Committee, June, 1937, p. 278.

[111] "Design for National Power Policy," *New Republic*, March 2, 1938.

special occasion in a particular area as a means toward achievement of some objective important to the national welfare, to gain which would effect a proper relation between costs and benefits in terms of social accounting. * * * In place of maximum money profits accruing to private ownership, the objective of public enterprise is maximum social benefits widely and equitably distributed."

Regarding the system of high dams, which Professor Mead states "is believed to have been built almost exclusively on account of power development," the testimony presented in the various engineering reports led the District Court, E.D. Tennessee, to state[112] its judgment that the improvement of the Tennessee River, from its mouth to Knoxville, by a series of low movable dams without power development, would have practically no effect on floods.

Referring to low-lift dams, it also declared that:

"Such a waterway would be inferior to the high-dam developments and would not permit the economical development of power. * * * The board of engineers pointed out that in addition to having no value whatever for flood control, the 32 low dams, although less expensive to construct than the high dams, provided a navigation channel inferior to the high dam plan. * * * It concluded that 'it is evident that the full utilization of the resources of this river for the public benefit requires its development of power and navigation.'"

No engineer should object to a yardstick. It may not be "clearly dishonest," as Professor Mead states, but only a question of the type of yardstick required to measure the objectives sought. Mr. Cooke has defined it in clear terms:[113]

"The advantages of public enterprise as a yardstick cannot be realized by attempting to set up a public enterprise in such a manner as to duplicate a private enterprise in every detail, and then comparing the two. They are essentially different kinds of institutions, with different objectives. Comparison of the costs of identical component parts of technical operations by a uniform system of accounting can indeed be useful; but comparison of the costs of a public enterprise in its entirety is neither realistic nor practicable because of the variables involved. For instance, public agencies obtain their money at low rates and almost without exception amortize their investments. The private utilities, by their failure to amortize capital-debt, laid themselves open to the recent collapse of equity values.

"It is a recognition of, and experiment with, the variables that is important. A public enterprise can make experiments and comparisons on many fronts that private enterprise cannot or will not make. It can explore such things as the advantages and disadvantages of mass consumption at low rates, the extent to which electricity can be used advantageously on farms, and the influence of productivity and the costs of good wages and superior working conditions. It can explore the part to be played by electricity as the 'coordinating agent' in the promotion of a comprehensive conservation program."

DANIEL W. MEAD,[114] PAST-PRESIDENT AND HON. M. AM. SOC. C. E. (by letter).—The writer has read with much interest the discussion that followed the publication of his paper. He feels that little can be gained by continuing a discussion on public works, the facts concerning which, in any exact or detailed way, have been so successfully and completely withheld from the public. The important question is not whether "this" or "that" will be accomplished by any of the various projects which have been thrust upon the American people without their desire or consent, but whether or not a new theory of economic procedure is to be inaugurated in this country and whether business relations shall be changed entirely by the destruction of utility and other business investments through Federal competition. There is, and can be, no doubt that any private business can be ruined and destroyed by Federal competition or by the competition of a municipal or district project which is subsidized by the Federal Government to the extent of almost 50%, and in which taxes can be eliminated and interest reduced to a mere fraction of that which must be paid by private investors. If this is the basis of determining the fair cost of a project or the basis of a so-called "yardstick," then there can be no doubt of the inability of the private corporations to compete. In all such public investments the cost of production is an unknown quantity which can be so manipulated that losses can be covered by taxes, and the "yardsticks" so limited that they will assure ruin to all those the Government (Federal, State, or municipal) would destroy.

---

[112] 21 Fed. Supp. 947, District Court, E.D. Tennessee.

[113] "Design for National Power Policy," *New Republic*, March 2, 1938.

[114] Prof. Emeritus, Hydr. and San. Eng., Univ. of Wisconsin; Cons. Engr., Madison, Wis.

The Administration can, if it will, force this country toward Communism, Socialism, Fascism, or any other such "ism" as its unscrupulous politicians may desire, under the plea of emergency or the excuse of furnishing work to the unemployed. This can be done as long as it can maintain its authority and power by subsidizing selfish individuals and communities who prefer personal profit to the public good and are influenced through public works paid for by tax money and public loans imposed upon the taxpayers on a basis that will not stand sound economic analysis.

The writer stands for a fair deal. He has no defense to offer for private dishonesty in either public utilities or private business; neither can he satisfy his ideals of honesty and integrity by approving unfair and dishonest procedure in Federal or other Government affairs because some private businesses may also have been unfair and dishonest. What is needed at this time is intelligence, honesty, and decency in both business and Government.

The writer does not believe that the country can spend itself out of this depression; neither does he believe that business and confidence can be restored and the depression vanquished by Government competition and the destruction of the investments of its citizens.

WILLIAM J. WILGUS,[115] HON. M. AM. SOC. C. E. (by letter).—A careful reading of the discussions of the Symposium has failed to change the views of the writer that the billion dollar quartet of public works, comprising the Passamaquoddy Tidal Power scheme, the Grand Coulee project, the Fort Peck Dam, and the Florida Ship Canal, are economically unjustifiable. In the case of the Florida Ship Canal the writer finds in the discussions not one single word in its defense. On the record it stands without merit and is unworthy of the further expenditure of the savings of the people of the United States.

DESIGN OF PILE FOUNDATIONS

By C. P. Vetter,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Hibbert M. Hill, Odd Albert, August E. Niederhoff, A. A. Eremin, Jacob Feld, John M. Coan, Jr., A. Agatz, D. P. Krynine, and C. P. Vetter.

Synopsis

It is intended, in this paper, to present rational methods for the determination of stresses in the individual piles of a pile foundation which supports a rigid structure such as a bridge pier or a hydraulic gate pier.

Athough it may be formulated in different ways, the purpose of the piles is obviously to minimize the settlement of the pier when it is acted upon by certain exterior forces. For the purpose of this investigation, the weight of the pier and other mass forces are considered exterior forces.

It is evident that the function of the piles is merely one of transfer. The statement is frequently made that the piles "carry" the structure; it would be more logical to state that the piles transfer the load from the structure to such strata of the foundation as are capable of carrying the load with a resultant settlement less than that prescribed for the structure. It is the subsoil that "carries" the load, and consolidation of soft material below the piles will inevitably contribute its share to the settlement of the structure whether or not piles are used.

If all external loads are vertical and the piles are also vertical, the piles transfer the load to deep layers in the subsoil. These layers may be more solid than the surface layers and may be so composed that they will support the load without material settlement. However, they may also be of essentially the same composition as the surface layers, but be more consolidated due to the superimposed load of the upper layers, so that the increased load of the structure may not cause objectionable settlements. Thus, the function of the piles is to transfer the load to the subsoil in such a manner that the compressibility of the upper layers of the foundation material affects the settlement of the structure only to a minor extent, if at all. Again, it may happen that the upper layers are of such composition that they will consolidate only slightly under load, whereas

---

Note.—Published in February, 1938, *Proceedings*.

[1] Engr., U. S. Bureau of Reclamation, Denver, Colo.

the lower layers are softer. Under such circumstances, there is obviously no reason for using piles; in fact, the driving of piles may so disturb the upper layers that their original compactness is destroyed with a resultant greater settlement of the structure than would have occurred had no piles been used.

If the external loads are horizontal and the piles are vertical, conditions are entirely different. There is, now, no transfer of load to deeper foundation layers, except such as is caused by the stiffness of the piles, which, especially in the case of wooden piles, is relatively small. The horizontal load is transferred mainly to the upper foundation layers by means of direct pressures between the sides of the piles and the soil. Although the upper layers may be solid enough to withstand these horizontal pressures without material deformation, in their original state, this may not be the case after driving or jetting adjacent piles in the often confined space under a pier. It is believed that, in the case of solid upper layers, the transfer of horizontal forces may better be aided by other methods, such as projections below the pier base extending into excavated trenches in the foundation. In the case of soft upper layers, it is apparent that no great reliance can be placed on the resistance to horizontal forces except such as is furnished by the stiffness of the piles themselves.

It is the purpose of this paper to present, and encourage the use of, methods of design permitting the construction of pile foundations that transfer loads in any direction, including horizontal loads, to deep-lying foundation strata.

It may be argued, in favor of the common practice of relying on vertical piles to resist horizontal loads, that single test piles often show a remarkable resistance to horizontal pulls. However, it often happens, and may be expected, that the deflection of large pile foundations will materially exceed that of a single test pile with a comparable load. This is believed to be due to two main causes: One is the fact that the ground around the single test pile has not been disturbed by the driving or jetting of adjacent piles; the other is the fact, readily verified mathematically or experimentally, that a group consisting of many piles connected to a rigid pier will deflect far more if subjected to a horizontal loading than a single pile acted upon by a horizontal force equal to the average load on an individual pile in the group. In the investigation described in this paper, needless to say, it has been necessary to make certain simplifying assumptions. It may be argued, in general, that the assumptions are so many that the results of the investigation have little, if anything, to do with the actual conditions and, in particular, that considerations from the point of view of soil mechanics have been neglected in favor of those of purely structural mechanics. This argument cannot be refuted in a general manner. There may be cases in which the results are valueless because of the assumptions made. It is believed, however, that in the great majority of cases the simplifying assumptions will have only little effect on the final result. As has been the case in other fields of engineering investigations, assumptions which are now thought necessary may gradually be eliminated by further investigation, so that ultimately a method of design will evolve that gives the entirely correct answer in all cases. Engineering progress is made in this manner.

NOTATION

The letter symbols adopted for this paper are defined where they first appear and are assembled for convenient reference in the Appendix.

GENERAL CONSIDERATIONS

Rational methods for the design of pile foundations that take into account the elastic deformations of the piles have been available for several years. That they are rarely used for practical design may be due to the fact that the general theory upon which they are based is somewhat difficult to follow and because the application to definite problems is often cumbersome. However, in nearly all practical cases, the conditions are simplified to such an extent that neither the necessary theory nor application offers any particular difficulties. The investigation presented herein is confined to such simplified conditions. Those who are interested in the theory in its general form, or who have special problems to solve are referred to the original texts to which references are given under the heading, "Acknowledgments." For the sake of clarity, the presentation, methods, and formulas differ somewhat from those of previous treatments of the subject. The basic principles, however, are not new and have been taken from the works cited.

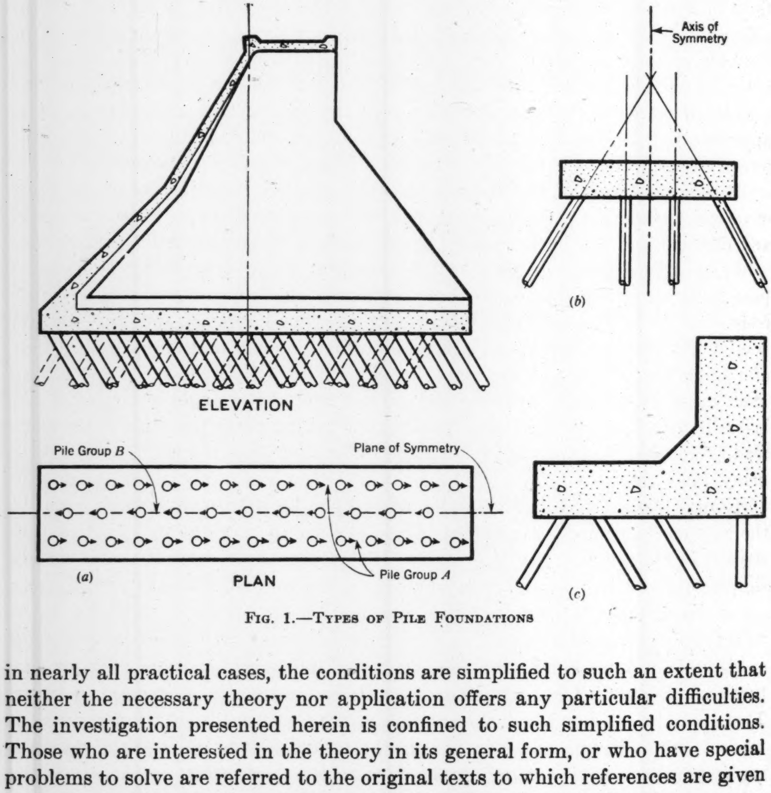

FIG. 1.—TYPES OF PILE FOUNDATIONS

The investigation is confined to two-dimensional systems; that is, to pile foundations having all piles parallel with, and symmetrical with respect to, a vertical plane of symmetry, and to structures in which the resultant of all outside forces, including dead loads, is located in the plane of symmetry. Although all piles are assumed parallel with this plane, they are not assumed to be parallel with each other. Three types of pile foundations are investigated: (*a*) Foundations consisting of two-pile groups, all piles in each group being parallel with each other (see Fig. 1(*a*)); (*b*) foundations having all piles symmetrical about a vertical line (pile bents) (see Fig. 1(*b*)); and (*c*) two-dimensional systems in general (piles in more than two directions and non-symmetrical) (see Fig. 1(*c*)).

It is assumed for all types that the structure on the piles (the pier) is infinitely stiff; that is, the internal deformation of the structure itself is disregarded.

Methods of procedure and formulas are first developed for the simple case in which each pile is considered as a column connected to the pier by means of a frictionless hinge, transmitting its load to the foundation material through a frictionless hinge located at some point of the axis of the pile. In many practical cases, such as bridge piers and gate piers in hydraulic structures, the error introduced by this assumption is insignificant. However, in some applications, such as pile bents for trestles, the error becomes of considerable magnitude. Therefore, methods are developed whereby the restraint of the pile heads in the pier and of the pile tips in the foundation material may be taken into account.

In the case of hinged piles the question arises as to the location of the lower hinge in the axis of the pile. Its location obviously depends on the material into which the pile is driven. If the pile is driven through loose material to firm ground the theoretical point of support would be approximately at the end point, and the so-called effective length of the pile would equal the actual length. If the pile is driven through uniform material so that its bearing capacity depends exclusively on friction, the theoretical point of support would be at some point above the pile tip. If it is assumed that the frictional resistance per linear foot of pile increases rectilinearly from zero at the top of the pile to a maximum value at the tip, the elastic deformation of the pile due to a load, P, applied axially at the top is determined by:

$$\Delta = \frac{1}{E\,A} \int_0^L \left(P - \frac{1}{2} \times f_x \right) dx \,\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which x is a distance measured from the base of the pier to some arbitrary depth along the pile; f_x is the frictional resistance per linear foot at that point; E is the elastic modulus of the pile material; and A is the cross-section area of the pile. However, due to the assumed rectilinear variation,

$$f = \frac{x}{L} f_t \,\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which f_t is the frictional resistance per linear foot at the tip of the pile.

Furthermore,

$$\frac{1}{2} f_t L = P \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

since the total frictional resistance must equal the pile load. Hence,

$$\Delta = \frac{1}{E\,A} \int_0^L \left(P - \frac{x^2}{L^2} P \right) dx = \frac{1}{E\,A} \frac{2}{3} L\,P \quad\ldots\ldots\ldots\ldots (4)$$

The deformation of a friction pile is thus the same as that of a pile of two-thirds the length, driven to firm ground, and its effective length is two-thirds of the actual length.

It is apparent that in the case of a pile, hinged both at its connection to the pier and at the point where it transfers its load to the foundation, the lateral resistance of the ground to movements perpendicular to the pile axis has been disregarded. In this case the exterior load on the pier is resisted solely by forces along the axes of the piles. On the other hand, there must be lateral resistance if the pile is considered restrained at one end or at both ends. The resistance must depend on the magnitude of the lateral displacement, on the depth below the surface, and, possibly, on several other factors, and it must be distributed in some manner along the entire length of the pile. For the sake of the investigation presented herein it is assumed that the total effect on the pier of the lateral resistance on the pile is represented by a lateral force (perpendicular to the pile axis) and a restraining moment, both acting at some point along the pile axis. Until the results of further research on the subject are available, the location of this point, the centroid of the lateral forces, can only be fixed by the judgment of the designer.

First, let it be assumed that all piles supporting the pier are hinged, and that the pier is acted upon by an exterior force in the plane of symmetry. The pier will then be displaced from its no-load position, due to the elasticity of the piles. The displacement may take the form of a translation or a rotation, or a combination of both. Since a translation may be defined as a rotation about some point at infinity, any small displacement may be considered a rotation. If the exterior force takes the form of a rotating moment, M (a force couple), the pier will rotate about a particular point, O, which is of special interest and is usually referred to as the elastic center of the pile group. If, on the other hand, the pier is acted upon by a resultant force going through Point O, the pier will rotate about a point at infinity; that is, the displacement will be a translation. This follows directly from Maxwell's general theorem of reciprocity.

Any arbitrary loading on the pier may be resolved into a force through the elastic center and a rotating moment; and, as has been shown, a force through this particular point will produce a translation and a moment will produce a rotation about the same point. Therefore, if the location of the elastic center, O, is known, and if the direction of the translation due to a given force through O has been determined, the problem of individual pile stresses is obviously reduced to finding the pile loads caused by a rotation about O and a translation in a given direction. In the investigation that follows the resultant of all stresses in a pile at its junction with the pier is designated the pile load or the pile reaction. The method followed to determine these quantities differs somewhat according to the type of foundation and will be dealt with for each individual type.

FOUNDATIONS CONSISTING OF TWO-PILE GROUPS

Hinged Piles.—Let the resultant of all outside forces, including dead load, be R and let the two pile groups be A and B, in Fig. 1(*a*). All piles in each group are parallel with each other and are assumed to be of the same length. Piles of Group A need not necessarily be of the same length as the piles of Group B.

In order to determine the location of the elastic center, give the pier an arbitrary small translation in a direction perpendicular to the direction of the piles in Group B. How this translation is brought about is, for the present, immaterial. As a result of the translation no loads will be induced in the piles in Group B, and all the piles in Group A will have the same load. The resultant of all pile loads will be a force parallel to the piles in Group A and going through the center of gravity of this group. Furthermore, a force, equal in magnitude and location but opposite in direction to this force, acting on the pier will produce a translation perpendicular to the direction of the piles in Group B. Next, give the pier a translation perpendicular to the direction of the piles in Group A. The resultant of all pile loads induced by the translation will be a force parallel to the piles in Group B and going through the center of gravity of this group; and a force, acting on the pier, equal in magnitude and location, but opposite in direction to the resultant, will cause a translation perpendicular to the direction of the piles in Group A. Two lines of force have thus been determined. An outside force acting on the pier along either one of these lines will produce a translation perpendicular to the other. An outside force going through the point of intersection of the two lines may be resolved into components along the two lines. Since each of the components produces translation without rotation, the force itself must also produce translation without rotation and, by definition, the point of intersection must be the elastic center.

The following rule may be established:

> Rule 1.—In a pile foundation consisting of piles in only two directions the elastic center is the point of intersection between lines drawn through the centers of gravity of the two-pile groups and parallel with the directions of the piles in the respective groups.

It is further evident that:

> Rule 2.—An outside force through the elastic center will result in loads on the piles which may be determined by resolving the force into components parallel with the directions of the piles in the two groups and dividing the magnitude of the components by the number of piles in the respective groups.

Pile loads due to a rotating moment may be found as follows: The moment will cause a rotation designated $\Delta\phi$ about the elastic center (Fig. 2). As a result, the length of each pile will be changed by an amount,

$$\epsilon = \rho\,\Delta\phi\sin\gamma = r\,\Delta\phi \qquad (5)$$

in which ρ is the radius vector to the top of the pile and r, the perpendicular distance from the elastic center to the pile. The reaction exerted by the pile due to the change in length is:

$$P_M = \frac{E\,A}{L}\,\epsilon = \frac{E\,A}{L}\,r\,\Delta\phi \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

FIG. 2

The moment of all the pile reactions with respect to Point O must equal the rotating moment: $M = \sum \frac{E\,A}{L}\,r^2\,\Delta\phi$, or,

$$\Delta\phi = \frac{M}{\sum \frac{E\,A}{L}\,r^2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

The load on an individual pile is then determined by:

$$P_M = \frac{E\,A\,r}{L \sum \frac{E\,A}{L}\,r^2}\,M \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

If M is positive in the clockwise direction and compression is considered positive, r is positive if it extends from the point of rotation toward the right and negative if it extends from the point of rotation toward the left. In Fig. 2, r is negative.

If all piles have the same length, the same cross-sectional area, and are of the same material:

$$P_M = \frac{r}{\Sigma\,r^2}\,M \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Let the number of piles in Group A be n_A and in Group B, n_B, and let the component of the resultant in the direction of the A-piles be R_A and in the direction of the B-piles, R_B. The load on any pile may then be found from,

$$P_A = \frac{R_A}{n_A} + \frac{r}{\Sigma\, r^2} M \qquad (10a)$$

and,

$$P_B = \frac{R_B}{n_B} + \frac{r}{\Sigma\, r^2} M \qquad (10b)$$

The summation, $\Sigma\, r^2$, should be extended over both the A-piles and the B-piles and the components, R_A and R_B, should be taken as positive when they cause compression in the corresponding pile group.

For design purposes the pile foundations can often be arranged so that the moment, M, becomes zero for two principal loadings. In a hydraulic structure, for instance, the point of intersection between the resultant for maximum water load and the resultant for dead load only should be made the elastic center of the foundation. This is done by drawing two lines through the point of intersection of the resultants parallel to the piles in each group and arranging the piles in each group so that the centers of gravity fall on these lines. The loads for resultants for intermediate water levels may be determined from Equations (10). For preliminary designs the load determination for intermediate resultants is rarely necessary.

Restrained Piles.—If the number of piles in the foundation is great and the rotating moment small, the quantity, $\Delta\phi$ (Equation (7)), becomes small, and the effect of restraint may be safely neglected. However, if the quantity, $\Sigma\, r^2$, is small the rotation may cause considerable bending in the piles with resultant changes in the direct pile loads. It is entirely possible to calculate the pile stresses, both due to axial load and bending, under these conditions. It is done by adding "dummy" piles perpendicular to each of the real piles, the location and length of the dummy piles to be such that the effect on the pier of an unrestrained real pile plus one or two unrestrained dummy piles is the same as that of the restrained real pile. The dummy pile was first introduced by Dr. C. Nökkentved.[5] After the locations and lengths of the dummy piles have been determined, the procedure of load determination is exactly as if all piles were real and unrestrained. The dummy piles are thus purely imaginary piles added for the purpose of facilitating the computations. Certain loads will be found on the dummy piles, and these loads represent the actual shears in the real piles. The addition of the dummy piles is the method whereby the effect of the restraint of the real piles is introduced in the computations.

The restraint of the piles may be classified as follows:

1.—Piles Restrained in the Foundation Material at Some Point of Their Axis and Connected to the Pier Through a Hinge.—It can be shown that the total effect of the pile foundation on the pier is not changed by considering the real piles hinged at both ends, providing a hinged dummy pile is added perpendicular to each real pile, intersecting it at the base of the pier. The dummy pile should be given an area equal to that of the real pile and an effective length,

$$L_1 = \frac{1}{3} \frac{A}{I} L_r^3 \qquad (11)$$

where A and I represent the area and moment of inertia, respectively, of the real pile, and L_r, the distance from the base of the pier measured along the axis of the real pile to the point where it is considered restrained.

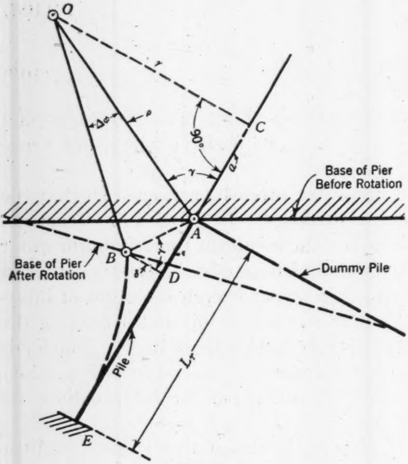

FIG. 3

In Fig. 3 is indicated a pier and one pile, AE, of a pile group. Give the pier a small rotation, $\Delta\phi$, about the arbitrary point, O. As shown in Fig. 3, the shortening of the pile is the distance $A\,D$, or,

$$\epsilon = \rho\,\Delta\phi \sin\gamma = r\,\Delta\phi \quad (12)$$

Furthermore, the lateral deflection of the pile is $D\,B$, or,

$$\delta = \rho\,\Delta\phi \cos\gamma = a\,\Delta\phi \quad (13)$$

in which a = distance from the top of the pile, measured along the axis of the pile to a perpendicular to the axis through the elastic center. The deflection, δ, of the pile will cause a lateral reaction on the pier,

$$H = \frac{3\,E\,I}{L_r^3}\,\delta \quad (14)$$

in addition to the axial reaction:

$$V = \frac{E\,A}{L}\,\epsilon \quad (15)$$

Inserting the value of δ from Equation (13):

$$H = \frac{3\,E\,I}{L_r^3}\,a\,\Delta\phi \quad (16)$$

However, the lateral reaction, H, may also be obtained by adding a dummy pile perpendicular to AE and intersecting the pier base at Point A, provided the length of the dummy pile is,

$$L_1 = \frac{1}{3}\,\frac{A}{I}\,L_r^3 \quad (17)$$

The load on this pile due to the rotation, $\Delta\phi$, would be:

$$P_1 = \frac{E\,A}{L_1}\,\delta = \frac{E\,A}{L_1}\,a\,\Delta\phi \quad (18)$$

Inserting the value of L_1 from Equation (17):

$$P_1 = \frac{3\,E\,I}{L_r^3}\,a\,\Delta\phi = H \quad (19)$$

Since the point, O, is chosen in an entirely arbitrary manner, the substitution of the dummy pile for the restraining action of the real pile is obviously permissible for any displacement of the pier. The stress in the real pile, due to the restraint, is equal to that of a cantilever restrained at Point E and acted upon by a force, P_1, the axial load on the dummy pile, acting perpendicularly to the real pile at Point A.

2.—Piles Restrained at the Pier and not Restrained in the Foundation Material.—The real piles may be considered hinged at both ends if a dummy pile is added to each real pile. The dummy pile should be perpendicular to the real pile and should intersect it at the centroid of the lateral reactions exerted by the foundation material on the real pile. The cross-section area of the dummy pile should equal that of the real pile, and its effective length should be:

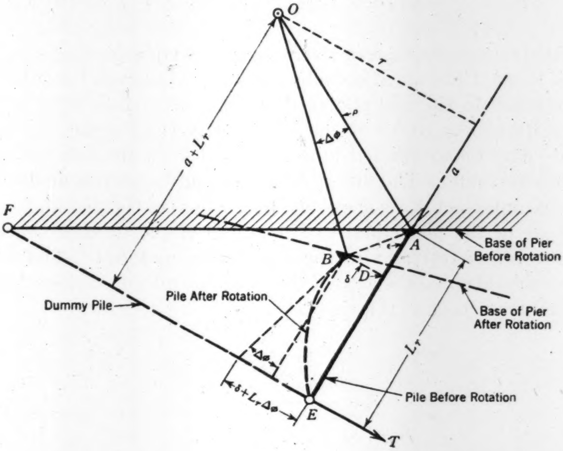

FIG. 4

$$L_2 = \frac{1}{3} \frac{A}{I} L_r^3 \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

in which L_r is the distance from the base of the pier, measured along the axis of the pile to the centroid of the lateral resistance in the ground. In Fig. 4 is indicated a pier and one pile, $A\,E$, of a pile group. Give the pier a small rotation, $\Delta\phi$, about the arbitrary Point O. Then, as before, the shortening of the pile is $A\,D$, or, $\epsilon = r\,\Delta\phi$; and the deflection is $D\,B$, or, $\delta = a\,\Delta\phi$. In addition thereto, the pile head receives a rotation equal to $\Delta\phi$.

The reaction on the pier due to the restraint is equal to that which, if applied at Point E, would deflect a cantilever, $A\,E$, restrained at Point A, a distance,

$$\delta_2 = \delta + L_r\,\Delta\phi \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

The force required to produce a deflection, δ_2, is:

$$H = \frac{3\,E\,I}{L_r^3}\,\delta_2 = \frac{3\,E\,I}{L_r^3}\,(\delta + L_r\,\Delta\phi) = \frac{3\,E\,I}{L_r^3}\,\Delta\phi\,(a + L_r) \ldots\ldots (22)$$

The lateral reaction, H, may also be obtained by adding a hinged dummy pile through Point E and perpendicular to $A\,E$, intersecting the pier base at Point F and having a length:

$$L_2 = \frac{1}{3}\frac{A}{I}\,L_r^{\,3} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

The load on this pile, due to the rotation, $\Delta\phi$, would be:

$$P_2 = \frac{E\,A}{L_2}\,\Delta\phi\,(a + L_r) = \frac{3\,E\,I}{L_r^{\,3}}\,\Delta\phi\,(a + L_r) = H \quad \ldots\ldots\ldots (24)$$

The stress in the real pile, due to the restraint, is equal to that of a cantilever restrained at Point A and acted upon by a force, P_2, the axial load on the dummy pile, perpendicular to the real pile at Point E.

3.—Piles Restrained Both at the Pier and in the Foundation Material.—The real pile may be considered hinged at both ends if two dummy piles are added to each real pile. The dummy piles should be perpendicular to the real pile and should intersect it, respectively, at the base of the pier and at a distance below the base of the pier equal to two-thirds of the total distance from the base to the point of restraint in the foundation material. The areas of the dummy piles should equal the area of the real pile and the effective length of the dummy pile intersecting at the base:

$$L_1 = \frac{1}{3}\frac{A}{I}\,L_r^{\,3} \quad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

and the effective length of the dummy pile intersecting at the two-thirds point:

$$L_2 = \frac{1}{9}\frac{A}{I}\,L_r^{\,3} \quad \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Since the two dummy piles are parallel, they will receive the same deformation for any translation and, for determining the elastic center only, may be combined into a single dummy pile with the same cross-section area as the real pile and an effective length:

$$L' = \frac{1}{12}\frac{A}{I}L_r^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

The combined dummy pile should intersect the real pile at a distance below the base of the pier equal to one-half the total distance from the base to the point of restraint. After the elastic center has been located, the two individual dummy piles should be used for the determination of pile loads. In Fig. 5 is indicated a pier and one pile, $A\ E$, of a pile group. The pile is restrained at both ends. Give the pier a small rotation, $\Delta\phi$, about the arbitrary point, O. Then the shortening of the pile, $A\ D$, is $\epsilon = r\ \Delta\phi$; and the deflection, $D\ B$, is $\delta = a\,\Delta\phi$. In addition, the pile head received a rotation equal to $\Delta\phi$.

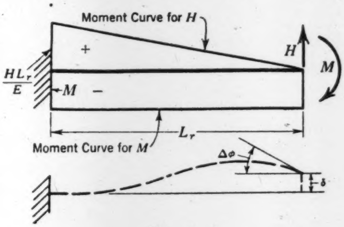

FIG. 6

The effect of the restraint on the pier would be a force, H, and moment, M, equal and opposite to a force and a moment which would produce, in a beam, $A\ E$, restrained at E, a deflection, δ, and a rotation, $\Delta\phi$, at Point A.

Considering Fig. 6 it will be seen that,

$$\delta = \frac{1}{E\,I}\left(\frac{1}{3}H\,L_r^3 - \frac{1}{2}M\,L_r^2\right) \ldots\ldots\ldots\ldots\ldots (28a)$$

and,

$$\Delta\phi = \frac{1}{E\,I}\left(-\frac{1}{2}H\,L_r^2 + M\,L_r\right) \ldots\ldots\ldots\ldots\ldots (28b)$$

Solving for H and M:

$$H = \frac{6\,E\,I}{L_r^2}\left(\frac{2\,\delta}{L_r} + \Delta\phi\right) = \frac{12\,E\,I}{L_r^3}\Delta\phi\left(a + \frac{L_r}{2}\right) \ldots\ldots\ldots (29a)$$

and,

$$M = \frac{12\,E\,I}{L_r}\left(\frac{\delta}{2\,L_r} + \frac{\Delta\phi}{3}\right) = \frac{6\,E\,I}{L_r^2}\Delta\phi\left(a + \frac{2}{3}L_r\right) \ldots\ldots (29b)$$

The moment, M, and lateral force, H, may also be obtained by adding a hinged dummy pile, D_1, through Point A perpendicular to $A\ E$ and having a length: $L_1 = \frac{1}{3}\frac{A}{I}L_r^3$; and a second hinged dummy pile, D_2, through Point G, perpendicular to $A\ E$, intersecting the pier at Point F, and having the length: $L_2 = \frac{1}{9}\frac{A}{I}L_r^3$. The load on Pile D_1 due to the rotation would be,

$$P_1 = \frac{E\,A}{L_1}\Delta\phi\,a = \frac{3\,E\,I}{L_r^3}\,a\,\Delta\phi \ldots\ldots\ldots\ldots\ldots\ldots (30a)$$

and the load on Pile D_2:

$$P_2 = \frac{E\,A}{L_1}\,\Delta\phi\left(a + \frac{2}{3}\,L_r\right) = \frac{9\,E\,I}{L_r^3}\,\Delta\phi\left(a + \frac{2}{3}\,L_r\right) \quad \text{......(30b)}$$

The sum of Equations (30*a*) and (30*b*) is:

$$P_1 + P_2 = \frac{12\,E\,I}{L_r^3}\,\Delta\phi\left(a + \frac{1}{2}\,L_r\right) = H \quad \text{............(31)}$$

The moment of P_1 with respect to Point A is zero and the moment of P_2 becomes:

$$P_2\,\frac{2}{3}\,L_r = \frac{6\,E\,I}{L_r^2}\,\Delta\phi\left(a + \frac{2}{3}\,L_r\right) = M \quad \text{.............(32)}$$

The stresses in the real pile, due to the restraint, may readily be determined by referring to Fig. 6 and utilizing the relationships, $H = P_1 + P_2$; and, $M = P_2\,\frac{2}{3}\,L_r$. Since the dummy piles constitute a pile group in a third direction, the pile loads cannot ordinarily be found by the method outlined for hinged piles, in only the two directions. Other methods are developed elsewhere in this paper which will permit solutions for this case.

PILE FOUNDATIONS WHICH ARE SYMMETRICAL ABOUT A VERTICAL LINE

Hinged Piles.—To determine the elastic center, give the pier a small horizontal translation equal to unity and toward the right (Fig. 7(*a*)). As a result the length of each pile will be changed an amount $\epsilon = \sin\alpha$; in which α is the angle of the pile with the vertical. The reaction exerted by the pile due to the change in length is:

FIG. 7

$$P_H' = \frac{E\,A\,\sin\alpha}{L} \quad \text{....................(33a)}$$

Due to symmetry, the resultant of the pile reactions must be a horizontal force:

$$R_H = \sum \frac{E\,A}{L}\,\sin^2\alpha \quad \text{....................(33b)}$$

Next give the pier a vertical translation, unity, downward (Fig. 7(b)). The change of length of each pile will be $\epsilon = \cos\alpha$; and the reaction:

$$P_V' = \frac{E\,A\cos\alpha}{L}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(34a)$$

Due to the symmetry, the resultant of the pile reactions must be a vertical force:

$$R_V = \sum\frac{E\,A}{L}\cos^2\alpha\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(34b)$$

FIG. 9

located in the axis of symmetry. The location of the resultant, R_H, may be found graphically by drawing a force polygon and a string polygon to the forces expressed by Equation (33a).

It may also be found analytically as follows: Lay a co-ordinate system with a X-axis vertical along the axis of symmetry with positive direction downward, and a Y-axis horizontal, at the base of the pier, if this is horizontal, with positive direction to the right. Let the distance from the point of origin of the co-ordinate system to the intersection of the piles with the Y-axis be y (Fig. 8(a)); then the X-co-ordinate to the elastic center is:

$$x_1 = -\frac{\sum \frac{E\,A}{L}\, y \sin\alpha \cos\alpha}{\sum \frac{E\,A}{L} \sin^2\alpha} \quad \text{(35a)}$$

If all piles have the same effective length and the same cross-section area, and are of the same material:

$$x_1 = -\frac{\Sigma\, y \sin\alpha \cos\alpha}{\Sigma \sin^2\alpha} \quad \text{(35b)}$$

The elastic center is thus a point on the symmetry axis having an X-co-ordinate of x_1. If a horizontal force, equal in magnitude and location to R_H but in the opposite direction, will cause a translation of unity and a pile load, P_H', then a horizontal force, H', through the elastic center will cause a pile load:

$$P_H = \frac{H'}{R_H} P_H' = \frac{\frac{E\,A}{L} \sin\alpha}{\sum \frac{E\,A}{L} \sin^2\alpha} H' \quad \text{(36a)}$$

Similarly, a vertical force, V', through the elastic center will cause a pile load:

$$P_V = \frac{V'}{R_V} P_V' = \frac{\frac{E\,A}{L} \cos\alpha}{\sum \frac{E\,A}{L} \cos^2\alpha} V' \quad \text{(36b)}$$

By the same reasoning as was used for pile foundations having piles in only two directions, the pile load due to a rotating moment is:

$$P_M = \frac{\frac{E\,A}{L}\, r}{\sum \frac{E\,A}{L}\, r^2} M \quad \text{(37)}$$

The total pile load is then $P = P_H + P_V + P_M$; or,

$$P = \frac{\frac{E\,A}{L} \sin\alpha}{\sum \frac{E\,A}{L} \sin^2\alpha} H' + \frac{\frac{E\,A}{L} \cos\alpha}{\sum \frac{E\,A}{L} \cos^2\alpha} V' + \frac{\frac{E\,A}{L}\, r}{\sum \frac{E\,A}{L}\, r^2} M \quad \text{(38a)}$$

If all piles have the same length and the same cross-section area and are of the same material,

$$P = \frac{\sin\alpha}{\Sigma \sin^2\alpha} H' + \frac{\cos\alpha}{\Sigma \cos^2\alpha} V' + \frac{r}{\Sigma\, r^2} M \quad \text{(38b)}$$

The positive direction of M has been given previously. The positive direction of H' is toward the right; and the positive direction of V' is downward. The positive direction of α is from the downward direction of the vertical, counterclockwise to the downward direction of the pile axis.

Comment.—Some interesting conclusions may be drawn from Equations (25) and (26). Since vertical piles do not help to resist a horizontal external force ($\alpha = 0$), structures subject to large horizontal forces should have as many battered piles as possible and the angle, α, should be made as great as possible. In structures where the rotating moment, M, is large, the quantity, $\Sigma\, r^2$, should be as large as possible. If $\Sigma\, r^2$ approaches zero the pile loads obviously approach infinity unless M is also zero. From Equation (7) it is seen that the rotation due to a moment increases as the quantity, $\Sigma\, r^2$, decreases; if, therefore, the piles, approximately, go through the same point, the rotation for a given moment would be large. The assumption that the effect of restraint may safely be neglected does not hold for this case and the stability of the pier depends almost entirely on the restraint and the stiffness of the piles.

It is worth noting that in one of the most commonly used pile bents (Fig. 8(*b*)) the center lines of the piles come very close to intersection at one point. Large displacements may be expected in a structure of this construction if it is subject to loads that do not pass through the elastic center.

Restrained Piles.—The restraint of the piles may be taken into account by the methods outlined previously. It should be noted that the addition of the dummy piles does not destroy the original symmetry so that after they have been added, the computations are exactly as given for hinged piles.

Two-Dimensional Systems in General

The procedure is very similar to that used for symmetrical pile groups. Give the pier an arbitrary, small horizontal translation, unity, toward the right. The reactions exerted by the piles due to the translation is given by Equation (33*a*). The location of the resultant of all the pile reactions may be found graphically by drawing a force polygon and a string polygon to the forces, P_H'. Let the resultant of these reactions due to a unit translation be R_H. If the pier is acted upon by an outside force, H', in the same location as R_H, but acting in the opposite direction, the resultant pile loads would be,

$$P_H = \frac{H'}{R_H} P_H' = \frac{E\,A}{L} \sin\alpha \frac{H'}{R_H} \qquad (39)$$

Since R_H is determined by graphical construction, P_H can be found for any value of H'. Next, give the pier an arbitrary, small vertical translation, unity, downward. The reactions exerted by the piles due to the translation is then given by Equation (34*a*). The location of the resultant of all the pile reactions may be found graphically by drawing a force polygon and a string polygon to the forces, P_V'. Let the resultant of these reactions, due to a unit translation be R_V. As a check it should be noted that the vertical projection of R_H equals the horizontal projection of R_V.

If the pier is acted upon by an outside force, V', in the same location as R_V, but acting in the opposite direction, the resultant pile reactions will be,

$$P_V = \frac{V'}{R_V} P_V' = \frac{E\,A}{L} \cos\alpha \frac{V'}{R_V} \qquad (40)$$

Since R_V is determined by graphical construction, P_V can be found for any value of V'. It follows from the determination of the forces, R_H, and R_V, that the point of intersection between them is the elastic center for the pile foundation. A moment, therefore, will produce rotation about this point and loads on the individual piles determined by Equation (37). The total load on a pile due to an outside force, with components, H' and V', in the directions opposite to R_H and R_V, respectively, and with a moment, M, about the elastic center is:

$$P = P_H + P_V + P_M = \frac{E\,A}{L}\left[\frac{H'}{R_H}\sin\alpha + \frac{V'}{R_V}\cos\alpha + \frac{r}{\sum \frac{E\,A}{L} r^2} M\right] \quad \text{..(41)}$$

The positive directions for M, α, and r have been defined previously. The positive directions for H' and V' are opposite to the directions of R_H and R_V.

If all piles are of the same length and the same material, the string and force polygons should be drawn to the forces: $P_H'' = \sin\alpha$; and, $P_V'' = \cos\alpha$, corresponding to the horizontal or vertical translations, $\Delta = \frac{L}{E\,A}$. Let the resultants of the pile reactions due to these translations be R_H' and R_V', respectively. If the pier is acted upon by outside forces, H' and V', in the same location but acting in the opposite direction of R_H' and R_V', the pile loads would be: $P_H = \frac{H'}{R_H'}\sin\alpha$; and, $P_V = \frac{V'}{R_V'}\cos\alpha$. The total pile load, in case all piles are of the same length and same material, is then,

$$P = \frac{H'}{R_H'}\sin\alpha + \frac{V'}{R_V'}\cos\alpha + \frac{r}{\Sigma r^2} M \quad \text{..............(42)}$$

It should be noted that in this general case the forces, R_H, R_H', R_V, and R_V', are not horizontal and vertical forces. They are the resultants of pile reactions due to horizontal and vertical translations. Only in the case of symmetrical pile foundations do they become horizontal and vertical forces.

Numerical Example

On Fig. 9 is shown a symmetrical pile bent consisting of four piles driven at a batter of 1 : 6 and spaced as shown. The piles are of reinforced concrete, 49 ft long, and driven 23 ft into fine sand. The cross-section areas of all piles are the same, and equal 331 sq in.; the moments of inertia of the cross-sections are 8 800 in.^{4} The effective lengths are $49 - 23 + \frac{2}{3}\,23 = 41.33$ ft. The pile bent is subjected to three loads: A dead load of 106 kips acting vertically in the axis of symmetry; a live load of 36 kips acting vertically 3.0 ft from the axis; and a wind load of 6.1 kips acting horizontally 7.35 ft above the base of the pier.

The pile loads are determined under the assumptions that all piles are: (1) Hinged both at the pier and in the foundation; (2) hinged at the pier and restrained in the foundation material; (3) restrained at the pier and hinged in the foundation material; or, (4) restrained both at the pier and in the foundation material.

The piles are numbered 1 to 4, inclusive, from left to right; the dummy piles for Assumption (2) are designated D_1' to D_4'; for Assumption (3), D_1'' to D_4''; and for Assumption (4), D_1' to D_4' at the base of the pier and D_1''' to D_4''' at the two-thirds point.

Table 1 contains all numerical values used in the computations, including the lengths of the dummy piles calculated from Equations (11), (20), (25), and (26). Table 2(*a*) gives the computations of pile loads under Assumption (1). The location of the elastic center is found from Equation (35*b*) and the pile loads from Equation (38*b*). Table 2(*b*) gives the computations of pile loads under Assumption (2). The location of the elastic center is found from Equation (35*a*), and the pile loads from Equation (38*a*). Since all piles have the same cross-section and are of the same material, the quantity, EA, cancels out in these two equations. Tables 2(*c*) and 2(*d*) give the corresponding computations under Assumptions (3) and (4), respectively. Zero load on a dummy pile indicates that the load is negligible.

A study of the pile loads due to the different external forces will reveal several interesting facts. Under all assumptions, Pile No. 2 gets tension for live load only; it is doubtful whether this result would have been anticipated had other, less rational, methods of load determination been used. Restraint in the foundation material only, has little effect on the pile loads. The effect of restraint in the pier is more pronounced and the effect of fully restrained piles is considerable. Had the horizontal distances between the piles been greater, the effect of all restraints would have been decreased.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the valuable assistance of Mr. W. A. Larsen and the constructive criticism contributed by him and other engineers

of the United States Bureau of Reclamation in connection with the preparation of this paper. The investigation was conducted in connection with the design of the Imperial Dam, of the Boulder Canyon Project.

He has also consulted, freely, the fundamental work done in this field of study by Messrs. T. Hultin,[2] P. Gullander,[3] H. M. Westergaard,[4] M. Am. Soc. C. E., and C. Nökkentved.[5] In addition the following investigators have treated various phases of the subject: A. Ostenteld,[6] H. Wünch,[7] T. Schultze,[8] A. Labutin,[9] P. Hedde,[10] and Franx.[11]

APPENDIX

Notation

The following symbols, defined where first introduced in the paper, are rearranged herein for convenience of reference. An effort has been made to conform essentially with "Symbols for Mechanics, Structural Engineering, and Testing Material,"[12] compiled by a committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = cross-section area of a pile;
a = distance from the top of a pile, measured along the axis of the pile, to a perpendicular to the axis through the elastic center.
E = modulus of elasticity of the pile material;
f = a function factor; the frictional resistance per linear foot of pile; f_x = the resistance at distance, x; and, f_t = the resistance at the tip of the pile;
H = a lateral reaction; H' = a horizontal force;
I = moment of inertia;
L = effective length of a pile; L_r = distance from base of pier measured along axis of pile to point where it is considered restrained;
M = a moment; a force couple;
n = a number; n_A = a number of piles in Group A;
P = a concentrated load; P_M = an additional load imposed by a change in pile length;
R = resultant of all external forces; R_H = a horizontal force, the resultant of pile reactions; R_V = a vertical force, the resultant of pile reactions;

r = distance from the elastic center to the axis of the pile;
V = axial reaction; V' = a vertical reaction;
x = a depth from the base of the pier to an arbitrary point along the pile axis;
y = the distance from the point of origin of the co-ordinate system to the intersection of the piles with the Y-axis;
α = an angle (see Fig. 2) of the pile with the vertical;
γ = an angle (see Fig. 2);
Δ = the elastic deformation of a pile due to a load, P, applied axially at the top;
ϵ = the change in length of pile;
ρ = a radius vector from the elastic center to the top of a pile;
ϕ = a rotation; $\Delta\phi$ = a small rotation;
δ = deflection of a pile.

DISCUSSION

Hibbert M. Hill,[13] Assoc. M. Am. Soc. C. E. (by letter).—A few years ago the writer had need of a method of analyzing batter-pile foundations and was impressed, in the search for a method, by the little attention writers in English have given this subject. In this respect the author has performed a very worth-while work. It is to be hoped also that the paper will give an impetus to the use of battered piles to resist lateral loads. The writer is convinced that, in general, it is unsafe practice to rely upon vertical piles to resist lateral loads. Never should any reliance be placed upon assumed frictional resistance between the base of a structure and the earth between the piles.

The writer, some years ago, adopted Krey's[14] method of analysis. This method approaches the subject in a manner sufficiently different from the author's approach to make a brief statement of it worth while.

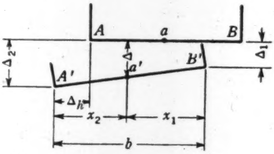

Fig. 10

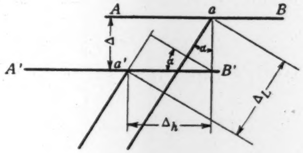

Fig. 11

The assumption is made that the axial deflection of an axially loaded pile is proportional to the applied load, and it is further assumed that the supported structure is rigid, so that the plane of the foundation remains plane after deflection. Consider a foundation, *A-B*, Fig. 10, which, under the action of a given loading, deflects to the position, *A'-B'*. Let a be a point on the foundation, then, Δ = vertical deflection of Point a; Δ_h = horizontal deflection of Point a; and, from the geometry of the figure,

$$\Delta = \Delta_1 \frac{x_2}{b} + \Delta_2 \frac{x_1}{b} \quad \text{.......................} (43)$$

Consider, further, a batter pile in a deflected foundation, Fig. 11: If Δ_h, Δ_1, and Δ_2 are small, and the length of the pile considerable, α, the angle of batter, remains approximately constant. Let the axial deflection of the pile be Δ_L, then,

$$\Delta_L = \Delta \cos \alpha + \Delta_h \sin \alpha \quad \text{...................} (44)$$

If P is the axial load on the pile,

$$P = k\,\Delta_L \quad \text{........................} (45)$$

---

[13] Supt., St. Anthony Falls Water Power Co., Minneapolis, Minn.

[14] "Erddurck, Erdwiderstand, und Tragfahigheit des Baugrundes," Berlin, 1932.

The coefficient, k, may be evaluated by such means as the author uses, or by means of loading tests on piles in the foundation under consideration.

If a computation of deflections is not important and all piles are alike, then the value of k need not be known, as the following equations can be solved directly for $k\,\Delta$. From Equations (43), (44), and (45), P may be evaluated for any pile if the three unknowns, Δ_1, Δ_2, and Δ_h, are determined (from the three conditions of equilibrium). Let V = the resultant vertical load acting on the foundation; and, H = the resultant horizontal load acting on the foundation, at the plane of the bottom of concrete; then:

$$V = \Sigma\, P \cos\alpha \quad \text{(46a)}$$

$$H = \Sigma\, P \sin\alpha \quad \text{(46b)}$$

and (see Fig. 11),

$$M = \Sigma\, x_2\, P \cos\alpha \quad \text{(46c)}$$

Substituting Equation (45) in Equation (46a):

$$V = \Sigma\, k\,\Delta_L \cos\alpha \quad (47)$$

Substituting Equation (44) in Equation (47),

$$V = \Sigma\,(k\,\Delta\cos^2\alpha + k\,\Delta_h \sin\alpha\cos\alpha) \quad (48)$$

Substituting Equation (43) in Equation (48):

$$V = \Sigma\left(k\,\Delta_1 \frac{x_2}{b}\cos^2\alpha + k\,\Delta_2\frac{x_1}{b}\cos^2\alpha + k\,\Delta_h\sin\alpha\cos\alpha\right) \quad (49)$$

or,

$$\frac{V\,b}{k} = \Delta_1\cos^2\alpha\,\Sigma\,x_2 + \Delta_2\cos^2\alpha\,\Sigma\,x_1 + n'\,b\,\Delta_h\sin\alpha\cos\alpha \quad (50)$$

in which n' is the number of piles battered at the angle, α.

Similarly,

$$H = \Sigma\,k\,\Delta_L\sin\alpha = \Sigma\,(k\,\Delta\sin\alpha\cos\alpha + k\,\Delta_h\sin^2\alpha)$$

$$= \Sigma\left(k\,\Delta_1\frac{x_2}{b}\sin\alpha\cos\alpha + k\,\Delta_2\frac{x_1}{b}\sin\alpha\cos\alpha + k\,\Delta_h\sin^2\alpha\right);$$

or,

$$\frac{H_b}{k} = \Delta_1\sin\alpha\cos\alpha\,\Sigma\,x_2 + \Delta_2\sin\alpha\cos\alpha\,\Sigma\,x_1 + n'\,b\,\Delta_h\sin^2\alpha \quad \text{(51a)}$$

and,

$$\frac{M_b}{k} = \Delta_1\cos^2\alpha\,\Sigma\,x_2^2 + \Delta_2\cos^2\alpha\,\Sigma\,x_1\,x_2 + b\,\Delta_h\sin\alpha\cos\alpha\,\Sigma\,x_2 \quad \text{(51b)}$$

From the known foundation dimensions and loads, Equations (50) and (51), may be solved for Δ_1, Δ_2, and Δ_h. Knowing these values, the stress in any pile may be determined from Equations (43), (44), and (45), or the equations may be solved for $k\,\Delta_1$, $k\,\Delta_2$, and $k\,\Delta_h$. By using these quantities in Equations (43), (44), and (45), P may be found directly. This course is only feasible when k is the same for each pile.

There will usually be at least two values of α involved in any batter-pile foundation. The most usual case involves plus and minus values of the same angle. In such a case Equation (50) would be written:

$$\frac{V\,b}{k} = \Delta_1 \cos^2 \alpha\, \Sigma\, x_2 + \Delta_1 \cos^2 \alpha'\, \Sigma\, x_2'$$
$$+ \Delta_2 \cos^2 \alpha\, \Sigma\, x_1 + \Delta_2 \cos^2 \alpha'\, \Sigma\, x_1' \cdots \text{etc.} \ldots\ldots\ldots\ldots (52)$$

and, similarly, for Equations (51). The unprimed values of x_1 and x_2 apply only to piles battered at the angle, α, whereas the primed values apply only to the piles battered at the angle, α'.

Apparently, Krey's method yields results that are somewhat different from those of the author. Applied to Assumption (1) of the author's numerical example, the writer obtains the following comparative values:

Pile No.	Author, Table 2	Writer
1	50.9	41.7
2	2.5	11.7
3	69.5	60.3
4	21.1	30.4

Like other writers on the subject, the author assumes deflections to depend purely upon the elastic properties of the piles. This assumption is tantamount to the assumption that all piles reach a rigid surface at their tips which, of course, is rarely the case. The true pile deflections are a compound of earth settlement, yield of the pile in the soil, and elastic deformation of the soil. Since the deflections upon which the stresses are based are small, and since the relative deflections at the edge and center of a foundation in a compressible soil may be of the same magnitude as, or of a greater magnitude than, the deflections found from the author's or the writer's formulas, the stresses obtained from any formula based upon purely elastic assumptions should be weighed in the light of the probable settlements.

However, analysis such as that given in the paper is a very necessary first approach to the problem (the best now available), and is far superior, say, to the method in which stresses in the batter-piles are first computed as if the piles were vertical, after which the horizontal thrust is based upon the stress thus computed and the sine of the batter angle. Such methods may lead to dangerous conditions, through a lack of realization of the true action of the inclined piles. The author (see heading, "Two-Dimensional Systems in General"), has pointed out one such possibility. The writer encountered another case in a design having piles battered only in one direction. Under the construction dead load there was danger of marked deformations, if not failure, due to the unbalanced thrust of the batter piles arising from the vertical load, a thrust which could not be balanced until the structure had been completed and backfilled.

The dummy-pile method of accounting for restraint is an ingenious one. The writer's method has been first to make a preliminary computation of deflections, as under the author's Assumption (1), and then on the basis of the deflections thus obtained to approximate the moments and shears in the piles upon the basis of equations such as those of Cummings,[15] or Chang,[16] or Timoshenko.[17] The shear at the base of the structure thus obtained is an additional horizontal force restraining lateral movement, and the moment obtained from these formulas may be added to the moments of the external loads. The pile moments serve to redistribute the external load, often in an important manner. That this occurs in foundations containing only vertical piles, but subject to lateral loads, is not generally realized.

The author has treated only foundations loaded in a single plane. The evaluation of stresses occasioned by eccentricities about both axes of the foundations is possible for many cases. Consider a pier, as shown in Fig. 12(*a*).

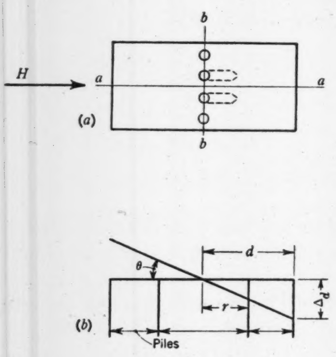

FIG. 12

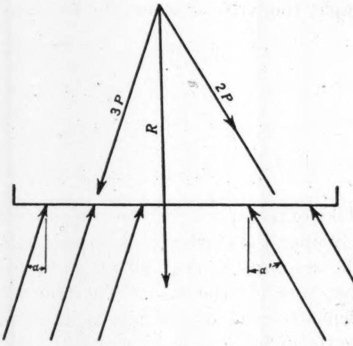

FIG. 13

The pile arrangement is assumed symmetrical about Axis *a-a*. The foundation contains vertical piles, and piles battered parallel to Axis *a-a*. The deflections due to H and V are first evaluated, neglecting eccentricity with respect to Axis *a-a*. Since the piles are symmetrical about Axis *a-a*, the moment in the plane normal to it will cause deflections symmetrical about this axis; thus: $M' = \Sigma\, P \cos\theta\, r = \Sigma\, k\, \Delta_L \cos\theta\, r = \Sigma\, k\, \Delta \cos^2\theta\, r = \Sigma\, k\, \Delta_d \frac{r}{d} \cos^2\theta\, r$; hence,

$$\Delta_d = \frac{M'}{\Sigma\, k \frac{r^2}{d}} \cos^2\theta \qquad (53a)$$

and,

$$\Delta = \frac{r}{d} \Delta_d \qquad (53b)$$

If these deflections cause no further deflection in the direction of H, they may be added directly to those previously determined, and from the result, the stresses may be evaluated. In the case shown, the lateral moment causes compression in the batter-piles on one side of Axis *a-a*, and tension, or rather reduction of compressive stress, in batter-piles opposite, of the same amount.

---

[15] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 255.

[16] *Loc. cit.*, p. 272.

[17] "Strength of Materials," Vol. II, p. 408.

The result is that the horizontal components of the batter-piles are no longer equal on both sides of Axis *a-a*, although H does not change. A couple is formed, therefore, tending to rotate the foundation in the horizontal plane. If this couple is resisted by external restraint as, for example, by adjacent structures, no movement parallel to Axis *a-a* can occur, and the deflections may be evaluated by superposition. It is of interest that the formation of such a couple may be prevented by battering the piles in pairs, one with the load and one against the load, in each row. The horizontal components in each row due to the lateral eccentricity are thereby balanced.

In general, it will be desirable that a foundation utilizing batter-piles contain piles battered in opposition to each other. In the contrary case, the vertical load during construction or at other times when there may be no balancing horizontal load may cause lateral movement of the structure due to the horizontal component of the batter-pile stress. Where piles are battered with, and against, the lateral load, those inclined in the direction of the load may, in the absence of sufficient vertical load on the structure, be subjected to tension—that is, to extractive forces. Although in many instances piles are capable of resisting considerable extractive forces, it is usually not desirable that such forces be permitted to occur, and they will not occur if the vertical load on the foundation is sufficiently large. The effect, then, is to cause a reduction of the compressive load, rather than a tension, and the pile inclined with the load is as effective in lateral resistance as a pile inclined against it.

All the piles in a foundation containing only vertical piles may be loaded equally when subjected to vertical load alone; and rotation in the vertical plane may be prevented, by designing the group so that the centroid of the piles is on the line of action of the resultant load. Such an arrangement will be most economical in its use of piles although not necessarily most economical of superstructure, as all piles will be equally loaded.

Batter-pile foundations may be designed in a similar manner, as the author has indicated. The resultant, R, of the applied loads, excluding the part of the horizontal load taken by the earth in lateral bearing against the piles, Fig. 13, is resolved into two components inclined to the vertical at the adopted angles of batter, α and α'. Each component is divided by the permissible pile load, P, to obtain the number of piles inclined at the respective angles, α and α'. The line of action of the two components of the resultant is made to act through the centroids of the two-pile groups. All piles will thus be loaded equally and the axial deflection of each pile will be the same. The deflection of the foundation will be vertical and parallel to its unloaded position. There will be a resultant horizontal movement, however, if α and α' are unequal.

It will be noted that the batter angle, α, affects both the number of piles required and their location. These factors, in turn, affect the dimensions of the superstructure. Furthermore, there is usually no reason, other than an economic one, why all piles should be loaded equally, as such cases can be solved by the general formulas, Equations (50), and (51). The principle illustrated by Fig. 13, however, will be found of assistance in determining the most economical over-all design.

Odd Albert,[18] Assoc. M. Am. Soc. C. E. (by letter).—Although interesting and constructive, there is nothing fundamentally new in this paper (as Mr. Vetter states under the heading, "General Considerations"), except that it may be the first time the subject has been treated in the English language. As indicated in his "Acknowledgments," various pile theories were first developed in Sweden. Professor Per Gullander,[19] of the Chalmers Institute of Technology, Gottenborg, published an article on the subject in 1902. In 1911, R. Ekvall,[20] of the Royal Institute of Technology, Stockholm, added valuable material; and Professor Gullander[21] appeared again in 1912 with his first book on the subject. The previous year, Torsten Hultin, of the Chalmers Institute of Technology, read his paper on "How to Design Pile Foundations,"[3] presenting an entirely new graphical method, which has been adopted for general use.

The writer was privileged to study under Professor Gullander, and he remembers well how this famous and beloved teacher modestly stated concerning the various pile theories: "If it requires one week to design a pile foundation by the Ekvall theory, my method will require one day, and the Hultin method will only require one hour." However, he did not mention that this theory could be applied to any combination of pile groups, whereas the Hultin method required at least one axis of symmetry.

The method presented by Mr. Vetter seems to be a combination of the Ekvall and the Gullander methods, with quite a number of important improvements, which will be apparent by comparison with the following review of the original Hultin Pile Theory. The writer has taken the liberty of including a few changes, which he thinks will help to clarify this method.

The Hultin Pile Theory.—The stresses in a pile group supporting a body are caused by a very small movement of this body. This movement, no matter how complicated it may be, can always be divided into two separate movements of the entire body: (1) As a unit in two given directions; and (2) a rotation of the entire body around a selected center.

Therefore, the loads on the piles will be caused by: (*a*) The movement of the body in one direction; (*b*) the movement of the body in another direction; and (*c*) the rotation of the body around some center.

Fig. 14(*a*) shows four piles or groups of piles sloped in three directions. Assume, first, that the body moves a distance, l_h, to the left. Then each pile head will move a distance that equals the length of this movement projected in the direction of the pile. These projected distances, u, are determined graphically in Fig. 14(*b*). It will be noticed that $u_1 = 0$, because Pile (1) is vertical. Then the stresses in the piles, caused by a horizontal movement, l_h, will become:

In Pile (1) (because $u_1 = 0$)

$$P_1^h = 0 \qquad (54a)$$

in Pile (2),

$$P_2^h = + k_2 u_2 \qquad (54b)$$

FIG. 14

in which k is a constant, depending upon the size and length of each pile. Therefore, it is only necessary to know the relation, $k_1 : k_2$, etc. Thus, if Pile (1) is twice as strong as Pile (2), $k_1 = 2\, k_2$. If all the piles are of the same strength, $k_1 = k_2 = \cdots k$.

The force polygon shown by Fig. 14(*d*) locates the string polygon in Fig. 14(*a*) (marked H'–1–2–3–4–H'). For a movement, l_h, the resultant to all the loads, H', on the piles is found to have the direction and magnitude shown in Fig. 14(*d*), and the location shown in Fig. 14(*a*) at the intersection of the first and the last strings (+ 1 and − 4) of the equilibrium polygon.

Applying the law of reciprocal displacements, as a movement of l_h causes a reaction, H', it is evident that a unit load applied along the H-direction in Fig. 14(*a*) will cause a horizontal movement of the body, thus creating stresses in the piles of $+\frac{k_2\,u_2}{H'}$, $-\frac{k_3\,u_3}{H'}$, and $+\frac{k_4\,u_4}{H'}$.

Assuming next that the body moves a distance, l_v, vertically down, each pile head will move a distance that equals the projected distance of this movement on a plane in the direction of the pile. This projected distance may be called b, and it is determined graphically in Fig. 14(*c*). (It will be noticed that $b_1 = l_v$.) Then the stresses in the piles will be:

Pile (1),

$$P_1^v = +\,k_1\,b_1 \qquad (55a)$$

Pile (2),

$$P_2^v = +\,k_2\,b_2 \qquad (55b)$$

Pile (3),

$$P_3^v = +\,k_3\,b_3 \qquad (55c)$$

and Pile (4),

$$P_4^v = +\,k_4\,b_4 \qquad (55d)$$

in which k is the same constant as in Equations (54), depending only upon the pile to which it refers. Thus, k_1 refers to Pile (1), etc. In all cases, only movements in the direction of the slope of the pile are considered, and, therefore, k may be called the unit pile resistance.

Draw the force polygon (Fig. 14(*e*)) that determines the direction and the magnitude of the resultant force, V', from all the pile loads, caused by a vertical movement, l_v, of the entire body. In the equilibrium polygon, marked V'–1–2–3–4–5–V' (Fig. 14(*a*)), the first and the last strings (+ 1 and − 5) determine the location of V'.

Therefore, a unit load applied along the V-direction in Fig. 14(*a*) will cause a vertical movement of the entire body, creating stresses in the piles of $+\frac{k_1\,b_1}{V'}$; $+\frac{k_2\,b_2}{V'}$; $+\frac{k_3\,b_3}{V'}$; and $+\frac{k_4\,b_4}{V'}$.

Finally, assume that the body rotates to the left around R. As this rotation is considered very small, the movements of the pile-heads may be considered straight, and, therefore, will be in direct proportion to the distance of each pile-head from the rotation center, R. This distance may be called c. As the position of this center is selected at the intersection of Piles (1) and (4), there will be no stresses in Piles (1) and (4) from this rotation. The pile loads will be:

Pile (1),

$$P_1^d = 0 \qquad (56a)$$

Pile (2),

$$P_2^d = +\,k_2\,c_2 \qquad (56b)$$

Pile (3) (rotation causes tension),

$$P_3^d = -k_3 c_3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (56c)$$

and Pile (4),

$$P_4^d = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (56d)$$

in which k again is the same constant as that used in the other movements.

The force polygon (Fig. 14(*f*)) gives the direction and magnitude of the resultant force, D', from all the pile loads caused from a rotation around the point, R. The equilibrium polygon, marked D'–1–2–3–D', gives the location of D'. Now, a unit load applied along the D-direction in Fig. 14(*a*) will create a rotation around R only, creating stresses in the piles, such as $+\frac{k_2 c_2}{D'}$, and $-\frac{k_3 c_3}{D'}$.

Characteristic Lines.—It will easily be seen that the three location-directions, H', V', and D' (called characteristic lines), are independent of the size of the movements, as well as the actual loading. They only depend upon the chosen directions of the two movements as well as the location of the rotation center, and the pile group itself. Therefore, this part can be computed once and for all with complete disregard to the loading. As soon as the characteristic lines are obtained, they can be used for all kinds of loading; and this is the important part in the Hultin pile theory.

Application to a Loading.—A force can always be resolved along three directions; therefore, dissolve the loading along the characteristic lines. The body will then move in two known directions, and rotate around a known center. As soon as H, V, and D are known, the stresses in various piles are easily determined. Hence, the loading resultant, N, is resolved into three components, H, V, and D, as shown in Fig. 14(*g*). The stress in Pile (2), therefore, will become,

$$f_2^H = +H\frac{k_2 u_2}{H'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57a)$$

In this expression, H is an actual load determined from the load, N, carried by the pile group, and given in Fig. 14(*g*). The ratio, $\frac{k_2 u_2}{H'}$, can easily be obtained by scaling these distances from Fig. 14(*d*)—first $k_2 u_2$ and then H'. Similarly, the load caused by the load, V, on Pile (2) becomes,

$$f_2^V = +V\frac{k_2 b_2}{V'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57b)$$

and that caused by Load (*d*) is,

$$f_2^D = +D\frac{k_2 c_2}{D'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57c)$$

Then the total load on Pile (2) will be the sum of Equations (57), with their signs. Hence,

$$f_2 = +H\frac{k_2 u_2}{H'} + V\frac{k_2 b_2}{V'} + D\frac{k_2 c_2}{D'} \ldots\ldots\ldots\ldots (58a)$$

and, similarly,

$$f_1 = 0 + V\frac{k_1\,b_1}{V'} + 0 \dots\dots \tag{58b}$$

$$f_3 = -H\frac{k_3\,u_3}{H'} + V\frac{k_3\,b_3}{V'} - D\frac{k_3\,c_3}{D'} \dots\dots \tag{58c}$$

and,

$$f_4 = +H\frac{k_4\,u_4}{H'} + V\frac{k_4\,b_4}{V'}0 \dots\dots \tag{58d}$$

It will be noted that all complicated computations are eliminated from this method, and that all the stresses can be obtained by simple calculations on the slide-rule.

Mr. Vetter has selected an unusually simple case to demonstrate his method. Its full possibilities, as compared with those of the original (Hultin), cannot be properly appraised until the author has demonstrated its application to the more complicated cases.

AUGUST E. NIEDERHOFF,[22] ASSOC. M. AM. SOC. C. E. (by letter).—The author's development of his subject is based upon assumptions that may be at variance with facts. His analysis also appears needlessly complicated and leads to values that are different from those obtained by the writer using only the resolution of forces into components that act upon the piles axial and normal to the axis.

It is not feasible to neglect soil mechanics in investigating the probable stresses in a pile foundation. The soil in which the piles are driven, the bearing at the tip (if it exists), and the bulb of pressure about the pile, are as much a part of the foundation as the pile itself and should be considered in any analysis. The author attempts to bulwark his analysis by considering the elastic deformation of piles and in so doing he loses sight of the fact that the stress, and, consequently, the elastic deformation, of the pile itself is only pertinent in exceptional circumstances. These circumstances obtain only when the total stress in the pile is less than the amount the foundation soil can stand. In soft yielding soils in which piles are used it is the passive resistance of the soil that is critical rather than the stress in the pile. This is particularly true if the soil is prevented from bulging upward under lateral movement of the pile by an overlying concrete slab.

In developing a simple case the author assumes that the pile acts as a column and is connected to the pier by means of a frictionless hinge. It is stated (see heading, "General Considerations") that: "In many practical cases, such as bridge piers and gate piers in hydraulic structures, the error introduced by this assumption is insignificant." In the writer's experience on bridge and gate pier foundations, wooden piles have been extended into the concrete about 2 ft and were considered fixed. The value in fixing this end of the pile was demonstrated during tests conducted in the fine sand, silt, and clay deposits on the right bank of the Mississippi River about five miles up stream from Redwing, Minn. (These tests were authorized by the District Engineer, U. S. Army Engineers, at St. Paul, Minn., in 1934.) Round wooden piles, about 30 ft long and about 12 in. in diameter, were driven in a vertical position and tested by applying horizontal loads to the top of the pile at the ground line. One pile top was unrestrained and the deflection at the ground line for a lateral load of 19 000 lb was 1 in. A similar pile, tested in the same manner, but with the top restrained, showed a deflection of only 0.36 in. for a lateral load of 18 000 lb. These tests indicated that if the top of the pile was assumed free whereas it was actually fixed, the error introduced would be about 250% for the materials used in the experiment.

---

[22] Civ. Engr., U. S. Army Engrs., U. S. Engr. Office, Portland, Ore.

The author also assumes that the frictional resistance per linear foot of pile increases rectilinearly from zero at the top of the pile to a maximum value at the tip. If the resistance to driving piles can be taken as an indication of the frictional resistance per linear foot of pile, personal observation would lead the writer to assume a parabolic variation rather than a rectilinear variation. However, in the case of vertical piles, driven in soil and supporting a concrete footing at the ground surface, the effect of lateral loads is believed to produce entirely different distribution of resistive forces. With the soil confined by the overlying slab the maximum resistance to horizontal movement is the passive pressure of the soil and is directly proportional to the pile deflection. The maximum pile deflection in this case occurs at the ground surface near the top of the pile and becomes smaller toward the tip of the pile. The distribution of resistance to horizontal loads, therefore, can be assumed as a maximum value at the top of the pile and a minimum value somewhere near the tip.

The depth in the foundation soil at which a pile can be considered fixed or hinged depends upon the material and dimensions of the pile and the character of the soil in which it is driven. Discussions[23] of a paper by Lawrence B. Feagin, M. Am. Soc. C. E., fix this point for these tests mathematically, and the paper substantiates the tests with recorded measurements. It is not necessary to assume fixation or hinge action at a point two-thirds of the pile length, as the author has done, when a series of tests will fix this point definitely.

The use of dummy piles to aid in the analysis of a complicated pile foundation with restrained pile ends is recognized as a convenient tool. However, for the more simple systems it is believed that dummy piles add to the difficulty in determining actual pile loads. The numerical example given shows that the computations and procedure are involved. Using Fig. 9, the writer computed the total vertical force acting on the pile bent at 142 kips. The net moment of all external forces above Plane Y and about the top of Pile No. 4 has been computed as 844.165 ft-kips. The eccentricity, e, of the point of application of the resultant force from the center of gravity of the system of pile tops is $\frac{844.165}{142} - 5.5 = 0.44$ ft. The vertical load taken by any one of the four piles can be obtained from the formula:

---

[23] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 255.

$$P = \frac{V'}{n} \pm \frac{V' e c}{I_g} \dots\dots\dots\dots\dots\dots\dots\dots (59)$$

in which c = the distance from the center of gravity of the system to the center of the pile; and I_g = the moment of inertia of the pile system about its center of gravity.

Since the piles in the example are of the same cross-section, each value of A can be considered as unity and the moment of inertia, I_g, of the pile system about Plane X equals $2\,(5.5)^2 + 2\,(1.5)^2 = 64.8$. Substituting these values in Equation (59), the vertical loads are found to be as listed in Column (2), Table 3.

TABLE 3.—PILE LOADS, IN THOUSANDS OF POUNDS OR KIPS

Pile No. (1)	Vertical load (see Equation (59)) (2)	Axial load (see Equation (60a)) (3)	Normal load (see Equation (60b)) (4)
1....	40.80	39.8	8.4
2....	36.51	35.7	7.5
3....	34.49	34.2	4.2
4....	30.20	30.0	3.7

For comparative purposes, the loads on the piles are axial (P_a) and normal (P_n) to the axis, expressed, respectively, as:

$$P_a = P \cos(\alpha \pm \theta) \dots\dots\dots\dots\dots\dots (60a)$$

and,

$$P_n = P \sin(\alpha \pm \theta) \dots\dots\dots\dots\dots\dots (60b)$$

The angle the resultant force makes with the vertical is $\frac{6.1}{142} = \text{arc tan } \theta$. The value of θ in the example is 2° 28′ and the value of $\cos \theta$ is so close to 1 that no correction of the vertical pile load need be made for the effect of the small horizontal force. The angle of batter of the piles is given as α and is equal to 9° 28′. Values of P_a and P_n, as computed from Equations (60), are given in Columns (3) and (4), Table 3. These values differ materially from those obtained by the author, and it is believed that the introduction of a dummy pile into the analysis obscured the author's computations.

Mr. Vetter is to be commended for a refreshing review of pertinent factors entering into the design of a pile foundation as recorded in the "Synopsis" of his paper.

A. A. EREMIN,[24] ASSOC. M. AM. SOC. C. E. (by letter).—Formulas for computing stresses in the piles of a pile foundation are developed in this paper. Mr. Vetter has simplified the computations by combining them with graphical construction, and the resulting process is simple if applied to piles in symmetrical pile footings. However, with the present application of mechanical calculating machines, a more direct method of computing stresses in more complicated cases is often desirable.

---

[24] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

Stresses may be computed by three equations derived from statics. Assuming the origin of the co-ordinates at a distance, y_1, above the bottom of a pile footing, the equations may be written (see Fig. 15),

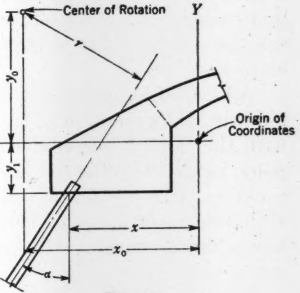

Fig. 15

$$H = \Sigma\, P \sin \alpha \ldots\ldots\ldots (61a)$$

$$V = \Sigma\, P \cos \alpha \ldots\ldots\ldots (61b)$$

and,

$$M = \Sigma\, P\, x \cos \alpha + y_1 \Sigma\, P \sin \alpha \,.\,. (61c)$$

in which,

$$P = \frac{E\,A}{L} r\, \Delta\, \phi \ldots\ldots\ldots (62a)$$

and,

$$r = (x_0 - x) \cos \alpha - (y_0 - y_1) \sin \alpha \,.\,. (62b)$$

and x_0 and y_0 are co-ordinates of the center of rotation. Solving Equations (61) simultaneously, unknown co-ordinates of the center of rotation and stresses in piles may be determined. Forces at the restrained ends of piles may be treated as explained in the paper.

Designers are often required to compute the elastic deformation in structures. Therefore, Mr. Vetter's paper is timely and creditable.

Jacob Feld,[25] M. Am. Soc. C. E. (by letter).—The purpose of piles is to transfer the base reactions of a footing to a soil that can carry such loads with settlements not exceeding the permissible values. Any resultant load can be resolved into a moment, and vertical and horizontal forces. The requirements of statics are the prime condition for any determination of what loads each pile (or group of piles) transfers to the carrying soil layers.

If all loads are vertical and the pile group is symmetrically spaced about the center of gravity of the loading, and if the footing may be considered a rigid body, the distribution of loads is uniform among all the piles. If the center of the pile group does not correspond with the center of the loading, the true distribution must take into account the eccentricity of loading, and also the compressibility of the piles and the settlement of each pile tip under the unequal loadings. The problem now falls into the class of indeterminate structures.

If all loads are vertical and if some or all of the piles are not vertical (battered) either the vertical load is transferred by skin friction or the pile is affected by a vertical couple. If the soil is sufficiently resistant to provide the skin friction in the immediate depths below the footing, no piles would be needed. In the other case, the lower end of the piles are embedded for a comparatively short distance in a soil much more resistant than that directly below the footing. A vertical couple acting on a pile can only be balanced by a horizontal couple resulting from a reverse type of deflection curve in the distance of resistant embedment.

---

[25] Cons. Engr., New York, N. Y.

Unless special details are insisted upon, the usual short pile embedment into a footing is not a rigid, moment-transferring (restrained) joint, nor is it a hinged joint. Such a connection is sufficient to transfer the horizontal loads from footing to piles. A horizontal load acting on a vertical pile can only be balanced by two unequal horizontal reactions with opposite directions. In no other way can the requirements of statics be satisfied, namely, equality of forces and of moments.

A horizontal load acting on a batter pile has the same effect as on a vertical pile with the exception of the unusual case in which the resultant load is axial with the sloping pile center. As has been well proved by tests on telegraph poles, as well as full-sized piles and sheet-piling, even short embedment of piles provides large horizontal strength. The greater cost of batter piles, together with the uncertainty of the fixed direction of the resultant loads, makes it advisable to consider such horizontal strength of piles before deciding on the use of batter piles.

Driving piles in a weak soil, without being certain that there is sufficient embedment in a resistant soil layer to take care of horizontal loads, is a common error. The result is a "creep" of viaducts, tipping of abutments, twist, and tip of towers.

The author carefully enumerates a number of the fundamental ideas in pile foundations, but his paper is really a mathematical study of the design of piles as elastic and static members. The final solution of a pile-foundation problem must take into account the fact that resistance is a function of the deformation resulting from load. The assumption (see heading, "General Considerations") that the effective length of a pile is independent of the load imposed, does not agree with the known action of soils. If sufficient resistance can be developed at the upper length of a pile, the lower part will be dormant. Distinction must be made between the actual soil resistance or friction and the latent maximum values. The distribution of one is not the same as that of the other. In this respect, soils are not elastic bodies.

The author's paper is excellent if restricted to the design of trestle or tower legs, or even for that part of piles above a resistant soil layer; for sub-surface design problems, the solution is only an approximation.

JOHN M. COAN, JR.,[26] JUN. AM. SOC. C. E. (by letter).—In focusing the attention of many engineers on the idea of the "dummy pile," the author is to be commended. It is recognized as a convenient tool in that it enables the designer to predict the pile moments under certain conditions of restraint, whereas, many methods used to-day neglect or, at most, approximate these moments.

In so far as practical applications are concerned, the theory is incomplete in that certain factors pertinent to intelligent design have not been included. For example, the inability to determine, with any degree of accuracy, the location of the point of pile restraint in the foundation and the failure to take into consideration the characteristics and confinement of the surrounding soil make it advisable to design with a liberal margin of safety. Such an analysis as Mr. Vetter presents might be applied to towers, pedestals, or similarly supported bodies with laterally unsupported elements or, more specifically, to pile piers passing through alluvial or practically non-resistant materials to resistant strata.

---

[26] Stress Analyst, Glenn L. Martin Co., Middle River, Md.

The author's treatment of the dummy-pile method is restricted to what amounts to two-dimensional arrangements in which the piles are parallel with, and symmetrical with respect to, a vertical plane of symmetry, and in which the resultant of the dead and applied loads lies in the plane of symmetry. If the plane of loading remains coincident with the plane of symmetry, such an analysis might be extended to include the case of a three-dimensional system in which the piles are symmetrical with respect to a vertical plane of symmetry, but not parallel to it. In this case the individual piles may be projected into the plane of symmetry, analyzed, and the results thus obtained corrected by the ratios of the true to the projected lengths. Furthermore, in the event of an arrangement having no vertical plane of symmetry, if the piles are of such section that each has equal moments of inertia about two mutually perpendicular axes, and if the resultant of the applied loads lies in a vertical plane which contains the centroid of the pile group, the piles will deflect in planes whose horizontal traces are parallel to the plane of loading. Such a condition may be analyzed as if a vertical plane of symmetry existed and coincided with the plane of loading.

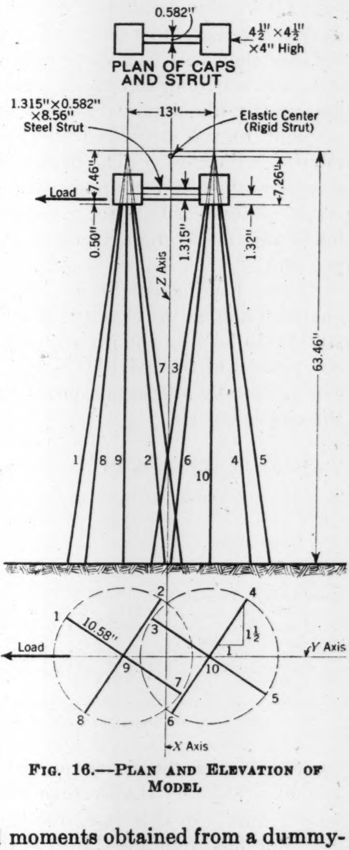

FIG. 16.—PLAN AND ELEVATION OF MODEL

The writer has made an extensive model analysis[27] of such a case and, although the pile arrangement studied was unique, it is considered worth mentioning because the axial loads and end moments obtained from a dummy-pile analysis agree reasonably well with the experimental results.

---

[27] "Model and Theoretical Analyses of a Tubular Pile Bridge Pier," by John M. Coan, Jr.; an unpublished essay submitted as partial requirement for the degree of Master of Civil Engineering, at The Johns Hopkins Univ., Baltimore, Md., May, 1938.

The model (Fig. 16) was one-fortieth scale and consisted of two groups of five symmetrically arranged tubular steel piles, each having an outside diameter of 0.757 in. and a wall thickness of 0.030 in. The piles were fixed in concrete at their bases, and in mortar caps at their upper extremities. These caps were connected by a non-rigid rectangular strut which permitted the transfer of loads and caused the action of the two groups to be interdependent. The points at which the piles were fixed corresponded to the arbitrarily located points of restraint mentioned by Mr. Vetter under the heading, "General Considerations." No attempt was made to simulate the resistance to lateral displacement that the alluvial materials, through which the prototype piles are to be driven, would offer. In view of the elasticity of the strut, it was necessary to correct the results obtained from a dummy-pile analysis because they had been determined under the assumption that the supported structure was infinitely rigid. This correction was made by cutting the strut, finding the unbalanced moment on each pier cap, and then distributing this moment to the strut and to the piles in that group in proportion to their relative stiffnesses. (The batter of the piles permitted only a negligible sidesway for which it was unnecessary to correct the distributed moments.) The result of this elastic strut correction was an inappreciable change in the axial loads and an average increase in the maximum pile moments of about 20 per cent.

Three loading conditions—dead + live + impact, ice, and wind—were analyzed and, in the case herein illustrated, a 120-lb ice load, corresponding to a 200 000-lb load on the prototype pier, was applied as shown. Table 4 gives a comparison of the axial loads and maximum bending moments as determined experimentally and as computed by the dummy-pile method and corrected for the elastic strut.

TABLE 4.—EFFECTS OF A 120-POUND ICE LOAD ACTION ALONG THE *Y*-AXIS

Description	Pile Nos.									
	1	2	3	4	5	6	7	8	9	10
Axial Load, in Pounds:										
Measured........	−141.1	108.2	−168.2	93.7	135.0	−110.9	163.3	−89.2	8.4	− 7.1
Computed.......	−135.2	111.9	−159.4	87.3	135.2	−111.9	159.4	−87.3	12.3	−12.3
Maximum Moment,* in Inch-Pounds:										
Measured........	12.7	11.3	11.1	11.5	10.7	10.4	8.4	13.3	9.5	9.2
Computed.......	10.4	10.5	9.2	9.4	9.2	9.3	10.4	10.5	10.5	9.4

* The pile moments are either positive or negative.

The average difference in axial loads, except the lightly loaded verticals, is just over 3% and the average variation in the maximum moments is within 16 per cent. In this case, due to portal action, the bending stresses are considerably less than one-third the total stresses and the differences between the measured and the computed bending moments are reduced in importance. Under the condition in which equal loads were applied at the centroid of each group and parallel to the *X*-axis, the displacements of the pile groups were independent of the strut, the end moments were of a much greater magnitude, and a closer agreement between the analytical and experimental moment determinations was found, the average difference being about 1 per cent.

A. AGATZ,[28] ESQ. (by letter).—The formulas and principles of design given by the author are, in fact, applications, to special and simple cases, of the methods developed by Dr. Nökkentved.[5] It is fortunate that these applications have permitted the emphasis of certain fundamental rules and that Mr. Vetter has demonstrated the importance of the rotating moment, M.

The main disadvantage in the application of Dr. Nökkentved's general methods, or any special method derived therefrom, is that only stresses in pile foundations that have already been designed, may be determined. Except in the case of pile foundations having piles in two directions only, or having three piles only, it is not possible, by the method presented by the author, to design a foundation for which it is assured beforehand that all piles will receive approximately equal loads for a given exterior loading. Making use of the same general assumptions as those of Dr. Nökkentved and the author, it is possible, however, by using a somewhat different approach to design a foundation consisting of piles in three directions, in which the loading on each individual pile is predetermined for one, and even for two, different exterior loadings. If more than these two loadings must be resisted, it will be necessary to choose Point O at or near the points of intersection of the resultants of the various loadings so as to reduce the magnitude of the rotating moment.

Since a moment always produces a rotation about the elastic center, with resultant non-uniform pile loads, it is desirable to design the pile foundation in such a way that the most unfavorable exterior load produces translation without rotation. The elastic center of a pile system which satisfies this condition falls on the particular resultant, R. Let the resultant that produces a translation (without rotation) in a direction forming an unknown angle, η, with the vertical, be designated R_η; and, let the load on an arbitrary pile as a result of the translation be P_n and the axial deformation of an arbitrary pile, be ΔL_n, then:

$$P_n = \frac{E_n\, A_n\, \Delta L_n}{L_n} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (63)$$

in which L_n and A_n are the length and cross-section area, respectively, of the pile, and E_n is the elastic modulus of the pile material. If all pile heads are at the same level and all pile ends likewise at the same level, at a depth, d, below the heads (see Fig. 17):

$$P_n = \frac{E_n\, A_n}{d}\, \Delta L_n \cos \alpha_n \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (64)$$

in which d is the vertical projection of the pile length, and α_n is the angle of the pile axis with the vertical. Let it further be assumed that all piles are of the same cross-section area and the same material. Since, in the investigation that follows, it is the ratios between the pile loads in the various groups that are of primary interest, the factor, $\frac{E_n\,A_n}{d}$, then may be given the value unity, without affecting those ratios, so that:

---

[28] Prof., Technische Hochschule, Berlin, Germany; tr. by C. P. Vetter, M. Am. Soc. C. E.

$$P_n = \Delta L_n \cos \alpha_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (65)$$

If the translation in the direction, η, is also unity:

$$\Delta L_n = \cos (\eta - \alpha_n) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (66)$$

and, it follows that,

$$P_n = \cos (\eta - \alpha_n) \cos \alpha_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots (67)$$

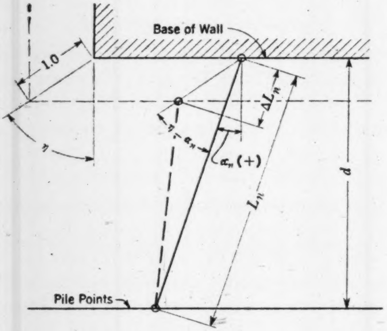

Fig. 17

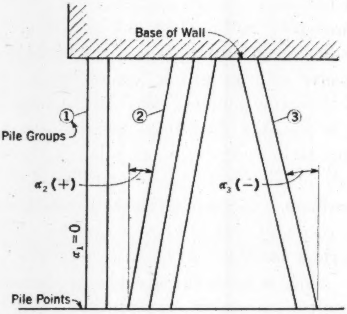

Fig. 18

If $\eta = 0$ (vertical translation), $P_n = \cos^2 \alpha_n$; and if $\eta = 90°$ (horizontal translation), $P_n = \sin \alpha_n \cos \alpha_n$. Let the loads in Pile Groups 1 and 3 (Fig. 18) be expressed as ratios, n and m, of the simultaneous pile loads in Group 2, all due to the same translation; thus, if $P_2 = \cos (\eta - \alpha_2) \cos \alpha_2$ (see Equation (67)): $\frac{P_1}{P_2} = n$; and, $\frac{P_3}{P_2} = m$.

Consequently,

$$P_1 = n\,P_2 = n \cos (\eta - \alpha_2) \cos \alpha_2 = \cos (\eta - \alpha_1) \cos \alpha_1 \ldots\ldots (68a)$$

and,

$$P_3 = m\,P_2 = m \cos (\eta - \alpha_2) \cos \alpha_2 = \cos (\eta - \alpha_3) \cos \alpha_3 \ldots\ldots (68b)$$

It will be assumed, furthermore, that the piles in Group 3 are in tension so that α_3 is negative, the numerical value in α_3 being designated $|\alpha_3|$. Equation (68b), then, is expressed as:

$$P_3 = \cos (\eta + |\alpha_3|) \cos |\alpha_3| \ldots\ldots\ldots\ldots\ldots\ldots\ldots (69)$$

Various relationships between α_1, α_2, α_3, η, m, and n may be derived from Equations (68a), (68b), and (69) as follows:

Case a.—Given, n, m, α_1, and α_2; let it be required to determine η and α_3. Then, from Equations (68*a*) and (68*b*),

$$\tan \eta = \frac{\cos^2 \alpha_1 - n \cos^2 \alpha_2}{n \cos \alpha_2 \sin \alpha_2 - \cos \alpha_1 \sin \alpha_1} \qquad (70a)$$

For $\alpha_1 = 0$, Equation (70*a*) becomes:

$$\tan \eta = \frac{1 - n \cos^2 \alpha_2}{n \cos \alpha_2 - \sin \alpha_2} \qquad (70b)$$

and, similarly,

$$\cos 2\,\alpha_3 = \frac{q \pm \tan \eta \sqrt{1 - q^2 + \tan^2 \eta}}{1 + \tan^2 \eta} \qquad (70c)$$

in which,

$$q = 2\,m\,(\cos^2 \alpha_2 + \tan \eta \sin \alpha_2 \cos \alpha_2) - 1 \qquad (70d)$$

In Equations (70) m and α_3 may be substituted for n and α_1, respectively, to determine the values of η and α_1.

Case b.—Given, $\alpha_1 = 0$, α_2, α_3, and m; let it be required to determine η and n. Similarly to Equation (70*a*):

$$\tan \eta = \frac{\cos^2 |\alpha_3| - m \cos^2 \alpha_2}{\sin |\alpha_3| \cos |\alpha_3| + m \sin \alpha_2 \cos \alpha_2} \qquad (71a)$$

and,

$$n = \frac{1}{\cos \alpha_2 (\tan \eta \sin \alpha_2 + \cos \alpha_2)} \qquad (71b)$$

Case c.—Given, α_1, α_2, α_3, and η; let it be required to determine m and n. Then, proceeding as in Case (*b*),

$$n = \frac{\cos (\eta - \alpha_1) \cos \alpha_1}{\cos (\eta - \alpha_2) \cos \alpha_2} \qquad (72)$$

For $\alpha_1 = 0$, Equation (72) becomes:

$$n = \frac{\cos \eta}{\cos (\eta - \alpha_2) \cos \alpha_2} \qquad (73a)$$

and,

$$m = \frac{\cos (\eta + |\alpha_3|) \cos |\alpha_3|}{\cos (\eta - \alpha_2) \cos \alpha_2} \qquad (73b)$$

Equations (73) are of particular interest for the design of pile foundations, and numerical values of m and n for varying values of α_2, α_3, and η are given in Table 5.

It should be noted that tension in the piles of Group 3 occurs only if, $\eta > 90° - |\alpha_3|$. The allowable load on a compression pile is P_2. Then, when the svstem has no rotation:

$$P_1 = n\,P_2 \qquad (74a)$$

and

$$P_3 = m\,P_2 \qquad (74b)$$

If the three axes of the pile groups can be placed so that the group components of the exterior resultant are always whole multiples of P_1, P_2, or P_3, the elastic center is on the resultant. The arrangement of the piles around a group axis is immaterial. However, the number of piles in each group must equal the aforementioned whole multiple. By group axis, is understood a line parallel to the center lines of the piles in the group and going through the center of gravity of the cross-section areas of the piles. In the investigation that follows, consideration is given only to the important case in which one group of piles is vertical ($\alpha_1 = 0$).

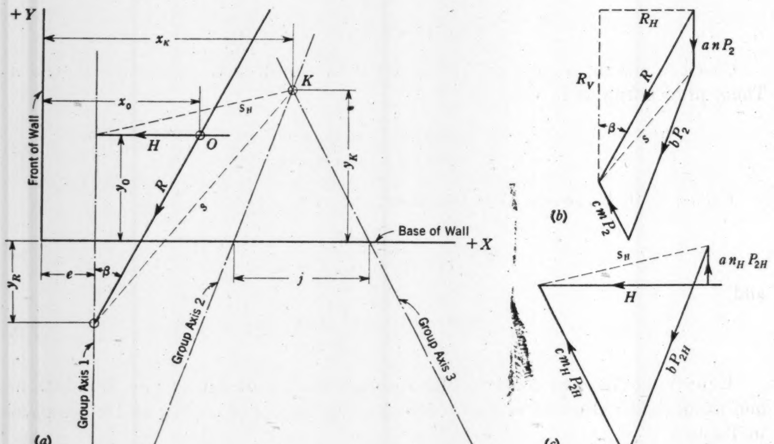

FIG. 19

From Table 5, in connection with general engineering considerations, possible values of m and n may be readily determined from assumed slopes, α_1, α_2, and α_3 of the three pile groups. The number of piles, a, b, and c, in each group may be found by means of a force polygon; thus, let a = number of vertical piles (slope, $\alpha_1 = 0$); b = number of battered compression piles (slope, α_2); and, c = number of battered tension piles (slope, $|\alpha_3|$).

In general, the magnitudes of the group reactions in the force polygon are not whole multiples of P_1, P_2, and P_3, but small remainders will occur in two of the forces. If such is the case, there will be a small rotating moment about the elastic center. As it is necessary to deal with whole numbers of piles, the nearest whole multiples, a, b, and c, may be selected and new values of m, n, and η calculated.

The known resultant, R (Fig. 19), and the pile reactions, $b\,P_2$, $a\,n\,P_2$ and $c\,m\,P_2$, must form a closed force polygon with known directions of the sides and, at the same time, must satisfy Equations (71). Values of m and n, therefore, may be obtained in terms of the pile batters, $\alpha_1 = 0$, α_2, and α_3. The number of piles, a, b, c, and the angle of R with the vertical, β, may also be determined from this condition.

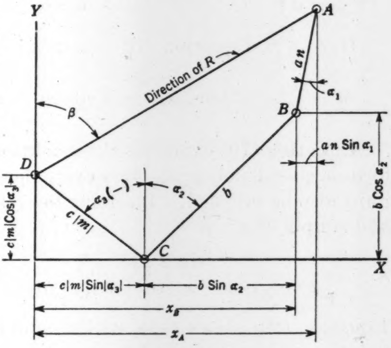

FIG. 20

Considering again the general case in which α_1 is not zero and m is negative, the force polygon will have the form indicated by $A\ B\ C\ D$ in Fig. 20. In drawing the force polygon, the scale has been chosen so that P_2 = unity; hence, $A\,B = a\,n$; $B\,C = b$; and, $C\,D = c\,|m|$. (Symbol $|m|$ indicates the numerical value of m.) Fixing a co-ordinate system as indicated, the equation for Line $D\,A$ is:

$$y = x \cot \beta + c|m|\cos|\alpha_3| \dots\dots\dots\dots\dots\dots (75a)$$

and the equation for Line $A\,B$ is:

$$y - b \cos \alpha_2 = \cot \alpha_1 \left[x - (c|m|\sin|\alpha_3| + b \sin \alpha_2) \right] \dots\dots (75b)$$

At the point of intersection, A, between the two lines, Equations (75) must both be satisfied. Designating by x_A as the abscissa to Point A, and eliminating y: $x_A \cot \beta + c|m|\cos|\alpha_3| - b \cos \alpha_2 = \cot \alpha_1 [x_A - (c|m|\sin|\alpha_3| + b \sin \alpha_2)]$; or,

$$x_A = \frac{c|m|\cos|\alpha_3| - b \cos \alpha_2 + \cot \alpha_1 (c|m|\sin|\alpha_3| + b \sin \alpha_2)}{\cot \alpha_1 - \cot \beta} \dots (76)$$

If the abscissa to Point B is x_B,

$$x_A - x_B = a\,n \sin \alpha_1 \dots\dots\dots\dots\dots\dots (77a)$$

and,

$$n = \frac{1}{a \sin \alpha_1} (x_A - x_B) \ldots\ldots\ldots\ldots\ldots\ldots (77b)$$

and, since $x_B = c|m|\sin|\alpha_3| + b \sin \alpha_2$:

$$n = \frac{1}{a \sin \alpha_1} \left[\frac{c|m|\cos|\alpha_3| - b \cos \alpha_2 + \cot \alpha_1 (c|m|\sin|\alpha_3| + b \sin \alpha_2)}{\cot \alpha_1 - \cot \beta} \right.$$
$$\left. - (c|m|\sin|\alpha_3| + b \sin \alpha_2) \right]$$

$$n = \frac{1}{a \sin \alpha_1} \left[\frac{c|m|\cos|\alpha_3| - b \cos \alpha_2 + \cot \beta (c|m|\sin|\alpha_3| + b \sin \alpha_2)}{\cot \alpha_1 - \cot \beta} \right]$$

and,

$$n = \frac{1}{a} \left[\frac{c|m|\cos|\alpha_3| - b \cos \alpha_2 + \cot \beta (c|m|\sin|\alpha_3| + b \sin \alpha_2)}{\cos \alpha_1 - \sin \alpha_1 \cot \beta} \right] \ldots (78)$$

If $\alpha_1 = 0$, Equation (78) becomes,

$$n = \frac{1}{a} [c|m|\cos|\alpha_3| - b \cos \alpha_2 + \cot \beta (c|m|\sin|\alpha_3| + b \sin \alpha_2)] \ldots (79)$$

Equation (79) expresses the condition that Forces *A B*, *B C*, *C D*, and *D A*, form a closed polygon. However, the deformation formulas, Equations (71), must also be satisfied. Inserting tan η from Equation (71*a*) in Equation (71*b*), and simplifying:

$$n = m \frac{\sin 2 \alpha_2}{2 \cos \alpha_2 \cos|\alpha_3|\sin (|\alpha_3| + \alpha_2)} + \frac{\sin 2|\alpha_3|}{2 \cos \alpha_2 \cos|\alpha_3|\sin (|\alpha_3| + \alpha_2)} \ldots (80)$$

Equation (80) shows that, with α_2 and α_3 given, and with $\alpha_1 = 0$, n is a linear function of m. If the pile foundation is to be subject to translation only and no rotation, Equations (79) and (80) must be satisfied simultaneously.

In Equation (79) the numerical value of m, designated $|m|$, has been used; and, it has been assumed that m is negative and that Pile Group 3 actually is subjected to tension. Substituting $|m|$ for m; assuming m to be negative also in Equation (80); and, equating the two expressions for n in Equations (79) and (80):

$$- |m| \frac{\sin 2 \alpha_2}{2 \cos \alpha_2 \cos|\alpha_3|\sin (|\alpha_3| + \alpha_2)} + \frac{\sin 2|\alpha_3|}{2 \cos \alpha_2 \cos|\alpha_3|\sin (|\alpha_3| + \alpha_2)}$$
$$= |m| \frac{c}{a} \cos|\alpha_3| - \frac{b}{a} \cos \alpha_2 + |m| \frac{c}{a} \sin|\alpha_3|\cot \beta + \frac{b}{a} \sin \alpha_2 \cot \beta \ldots (81)$$

After reduction:

$$|m| = \frac{\sin 2|\alpha_3| + 2 \frac{b}{a} \cos \alpha_2 \cos|\alpha_3|\sin (|\alpha_3| + \alpha_2) \times [\cos \alpha_2 - \sin \alpha_2 \cot \beta]}{\sin 2 \alpha_2 + 2 \frac{c}{a} \cos \alpha_2 \cos|\alpha_3|\sin (|\alpha_3| + \alpha_2) \times [\cos|\alpha_3| + \sin|\alpha_3|\cot \beta]} \ldots (82)$$

If the horizontal component of R is R_H and the vertical component, R_V:

$$\cot \beta = \frac{R_V}{R_H} \qquad (83)$$

If $\beta = 90°$, so that $\cot \beta = 0$:

$$|m| = \frac{\sin 2|\alpha_3| + 2\frac{b}{a}\cos^2 \alpha_2 \cos|\alpha_3| \sin(|\alpha_3| + \alpha_2)}{\sin 2\,\alpha_2 + 2\frac{c}{a}\cos^2|\alpha_3| \cos \alpha_2 \sin(|\alpha_3| + \alpha_2)} \qquad (84)$$

Equations (82) and (84) hold only if m is negative, or if $\eta > 90° - |\alpha_3|$. This can be verified by computing η from Equation (71*a*) after substitution of $-|m|$ for m. The value of n is determined from Equation (80) after having substituted $-|m|$ for m in the same manner; thus:

$$n = \frac{1}{2}\,\frac{\sin 2|\alpha_3| - |m| \sin 2\,\alpha_2}{\cos \alpha_2 \cos|\alpha_3| \sin(|\alpha_3| + \alpha_2)} \qquad (85)$$

It is evident from Fig. 20 that, for $\alpha_1 = 0$:

$$P_2\,(c|m|\sin|\alpha_3| + b \sin \alpha_2) = R_H \qquad (86a)$$

or,

$$P_2 = \frac{R_H}{c|m|\sin|\alpha_3| + b \sin \alpha_2} \qquad (86b)$$

Forces P_1 and P_3 are determined from Equations (74). The tangent, k_s, of the angle of Line s (Fig. 19) with the horizontal is determined by:

$$k_s = \frac{R_V - a\,n\,P_2}{R_H} = \frac{R_V - a\,P_1}{R_H} \qquad (87)$$

This line intersects the line of Resultant R on Pile Group Axis 1 (Fig. 19(*a*)). Line s is thus determined by the location of Pile Group Axis 1 and the slope is determined from Equation (87).

The point of intersection, K, between the axis of Pile Groups 2 and 3 must fall on Line s but the actual location on s may be determined from general engineering considerations.

Pile Foundation Having Its Elastic Center at a Given Point on the Resultant.—Any pile foundation that has its elastic center on the resultant of the exterior forces will be subject to translation only. However, it may be desirable that the elastic center should be located at a particular point on R. Let the point selected be O in Fig. 19(*a*). Apply an arbitrary force, H, to the pier, the force being given in magnitude and direction and passing through Point O. This force preferably should be horizontal. Compute $|m_H|$ from Equation (84) and n_H from Equation (85). To determine the slope of Line s_H (corresponding to Line s) rewrite Equation (87) for $R_V = 0$ and $R_H = H$; thus:

$$k_H = -\frac{a\,n\,P_2}{H} \qquad (88a)$$

Inserting P_2 from Equation (86*b*):

$$k_H = -\frac{n_H\,a}{c\,|m_H|\,\sin\,|\alpha_3| + b \sin \alpha_2} \qquad (88b)$$

Draw Line s_H with a slope, k_H, through the point of intersection of H and Pile Group Axis 1. The intersection of s_H and s is the particular point, K, at which Axes 2 and 3 must intersect to insure an elastic center at the particular point, O.

It can be shown in general that the lines, s, corresponding to the resultants, R (all of which go through the same point) also intersect in a single point. The points, O and K, are uniquely interdetermined. Instead of choosing a horizontal force through O for the determination of Point K, a force may be chosen which corresponds to some alternate possible loading on the structure. In general, it is advantageous to choose Point O at or near the points of intersection of the resultants of the various loadings so as to reduce the magnitude of the rotating moment.

Pile Foundations Having a Given Arrangement of the Battered Piles.—It is often of importance to determine the pile foundation so that the distance, j, between the points of intersection of Axes 2 and 3 with the base of the pier has a given value (Fig. 19(a)). If x_K and y_K denote the abscissa and ordinate to Point K, x_O and y_O, the corresponding quantities for Point O, are:

$$j = y_K\,(\tan\alpha_2 + \tan|\alpha_3|) \qquad (89)$$

or:

$$y_K = \frac{j}{\tan\alpha_2 + \tan|\alpha_3|} = j\,\frac{\cot\alpha_2\cot|\alpha_3|}{\cot\alpha_2 + \cot|\alpha_3|} \qquad (90a)$$

$$x_K = \frac{y_K - y_R}{k_s} + e \qquad (90b)$$

and,

$$y_O = y_K - k_H\,(x_K - e) \qquad (90c)$$

Distance e, the abscissa to the point of intersection of Axis 1 and the base of the pier, is usually fixed by engineering considerations; and y_R denotes the ordinate to the point of intersection of R with Axis 1. For the condition indicated in Fig. 19(a), y_R is negative and should be so inserted in Equation (90b); and k_s is determined from Equation (87) and k_H from Equation (88b). Since the elastic center is located on R, Quantity y_O determines that point uniquely; and x_K and y_K determine the point of intersection of Axes 2 and 3.

By fixing the elastic center, O, at some particular point of the resultant, R, or by fixing, beforehand, the characteristic quantity, j, of the pile foundation, and from this quantity computing the position of O on R, a satisfactory pile foundation can be designed to resist any given load. The method may be used also in case it is desired to design a pile foundation so that one or two different resultants produce a definite rotating moment, M, about the elastic center. In the latter case the resultant is translated a distance, $\frac{M}{R}$. The additional pile loads due to the rotating moment are as given by Equation (37) of the paper.

Design Procedure.—The following procedure has particular reference to the design of a retaining wall for which the horizontal component of the earth pressure is independent of the width of the base. Assume that the elevation of the pile tops, the length of the unit of the wall for which the pile foundation is to be designed, the permissible pile loads, the horizontal component of the exterior forces, and the length and cross-section area of the piles, are given.

It is required to determine the width of the base slab, the resultant vertical component of the exterior forces, the batter of the piles, the number of piles, the pile loads, and the arrangement of the piles. The steps in this procedure are:

(1) Determine the horizontal component, R_H, of the exterior forces.

(2) Select the pile batters.

(3) By varying the width of the base slab, select a value of the vertical component of the exterior forces, R_V, so that the corresponding R has a direction approximately equal to the direction of the battered compression piles.

(4) Determine the required number of piles by drawing the force polygon demonstrated in Fig. 19(*b*). In determining the required number of piles in Groups 1 and 3, approximate values of $|m|$ and n should be taken from Table 5.

(5) Compute the exact value of $|m|$ from Equation (84) checking to be certain that $\eta > 90° - |\alpha_3|$.

(6) Compute the exact value of n from Equation (85).

(7) Compute Unit Pile Load P_2 of a battered compression pile from Equation (86*b*).

(8) Draw Line s by computing its slope from Equation (87).

(9) Apply a horizontal load, H, to the pier, to be placed so that it intersects R at the desired location of the elastic center. Evaluate $|m_H|$ and n_H from Equations (84) and (85), respectively.

(10) Draw Line s_H by computing its slope from Equation (88*b*).

(11) If it is desired to fix the elastic center at a given point, determine Point K as the point of intersection of s and s_H.

(12) If it is desired that the distance, j (Fig. 19(*a*)), should have a given magnitude, determine the values of y_K, x_K, and y_O from Equations (90), respectively, or by means of graphical construction.

(13) Arrange the piles around their respective axes according to general engineering considerations.

Conclusions.—The author has presented a method for direct determination of the number of piles required in a pile foundation for a pier subject to two loading conditions, provided the foundation has piles in two directions only.

In the discussion presented herein, the writer has extended the method to cover pile foundations having piles in three directions. Complete formulas and method of procedure have been given for the case in which one of the three pile groups consists of vertical piles. This special case is of considerable practical importance in connection with the design of quay walls and other retaining walls.

D. P. KRYNINE,[29] M. AM. SOC. C. E. (by letter).—The design of a pile foundation (as of any other foundation) should be accompanied by an estimation of its probable settlement. Hence the design should include two determinations: (1) Stresses (pressures) on each pile; and (2) the probable settlement of the structure from these pressures. Mr. Vetter gives a method of finding pile pressures, but does not solve the second part of the problem. Apparently, some experimental work is needed; for instance, driving and loading of experimental piles, or some other field testing.

Methods of Finding Pile Pressures.—An historical outline of different methods of finding pressures under a pile foundation has been prepared by Professor A. Agatz [30] which, in conjunction with this paper, represents a comprehensive treatment of how the methods of design have been developed to their present stage.

The method of Culman, presented before 1870, was to break the resultant of forces acting at a pier in three components using an "auxiliary" force direction. Each component was the sum of pressures in all the piles running in that particular direction; and the stress in an individual pile was found by dividing that component by the number of corresponding piles. The well-known office method of trapezoidal pressure distribution under an eccentrically loaded retaining wall followed. Another method is to subdivide the vertical load proportionally to the distances between the piles.

These approximate methods have been replaced by methods in which the mathematical theory of elasticity is used. In his "Acknowledgments" Mr. Vetter gives several references to these methods; and his list might be amplified by the addition of Krey,[31] Jakobi,[32] and Mügge.[33] Mr. Vetter's assumptions and his general approach to the solution of the problem are similar to procedures used by previous investigators, as Mr. Vetter himself states.

The Rôle of the Earth Mass Under-Estimated.—The writer is not prepared to offer a theory of his own concerning the design of pile foundations. Therefore, he limits himself to expressing his general opinion on the methods which use elastic theories. It is assumed that the tips of the piles are in a steady position. This is because the piles are restrained or because there is a hinge either at the tip of the pile or at a certain depth as, for instance, at two-thirds the length of the pile. The former case is represented when piles reach rock or similar solid soil and the latter corresponds to friction piles. The writer doubts that, in a general case, the tips of the piles do not move. Stresses in the earth mass are not taken care of, except "passive resistance," which is sometimes mentioned. Deformations in the earth mass are not considered. In other words, the fact that an earth mass with piles driven in it in groups and subjected to lateral motion acts as a unit is neglected.

Isolated Piles Subjected to Lateral Forces.—The behavior of a group of piles under a foundation has not yet been investigated experimentally from this point of view; and some opinion thereon may be formed only by analogy with experimental data concerning the behavior of isolated piles and small groups of them. If an isolated vertical pile is subjected to the action of a horizontal force, it is bent, the "zero-point" (*Z*, Fig. 21) being located approximately at the third point of the restrained part, h. The accurate position of Point Z depends on several variables, among them being the elastic constants of the material of which the pile is made, and the earth material. This action would be the same whether or not the tip of the pile reaches rock, but it is not known very exactly what may happen if a heavy vertical load, P, is applied to a friction pile. It may be guessed that the lateral deflection, δ, will be smaller than without Load P.

[30] Der Kampf des Ingenieurs gegen Eide und Wasser im Grundbau, 1936, p. 166 *et seq.*

[31] Erddruck, Erdwiderstand und Tragfähigkeit des Baugrundes, Berlin, 1932, p. 162.

[32] Ost. Wochenschr. öff. Baudienst, 1909, p. 340.

[33] Beiträge zur zeichnerischen Lösung technischer Rechnungsaufgaben. Dissert., Hanover, 1906.

If the horizontal force, H', as shown in Fig. 21, is removed, the pile will regain its original (straight) shape, but will not be vertical any more due to a non-reversible (plastic) deformation of the soil. An analogous phenomenon probably occurs in the case of a pile foundation, and it may be that these plastic deformations are much greater than the elastic deformations considered in present methods of design.

The anchor of a bulkhead is bent as shown in Fig. 22. This gives some indication on the possible behavior of battered piles. There still will be a hypothetical hinge higher than the tip of a battered pile. The writer welcomes the idea of using battered piles for resisting horizontal forces and emphasizes the necessity of making pulling tests with such piles.[34]

Reinforced Earth.—The writer believes that when there are many piles under a structure subjected to the action of lateral forces, the stressed condition becomes exceedingly complicated, and that a simplified, rather conventional method of design should be used. In a pile foundation the earth is "reinforced," something like reinforced concrete.[34]

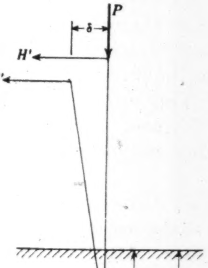

FIG. 21

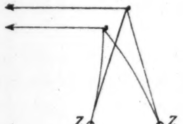

FIG. 22

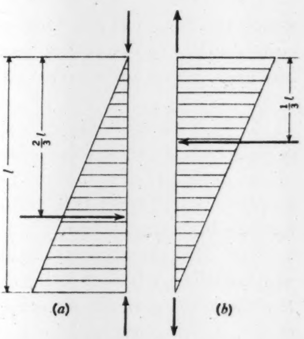

FIG. 23

Piles Designed as Columns.—In the light of several assumptions by Mr. Vetter the writer wishes to discuss his opinion as to the effective length of hinged piles. Mr. Vetter states that if the pile is driven through loose material to firm ground, the effective length of the pile will equal its length. This is not so, however, since the action of the "loose material" cannot be neglected and in reality is not neglected. To prove it, imagine piles 30 ft long standing vertically in the middle of the street, 3 ft apart, and carrying a substantial building. No engineer would dare to erect such a structure; however, in designing piles as columns exactly such a condition is considered. Cross-sections of the piles may be designed in this way. However, in computing the "effective length" some correction to the action of the adjacent soil must be introduced because in computing settlements the designer has no right to introduce arbitrary assumptions even if they are on the safe side. If he does so, his results will be in error.

---

[34] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 278.

Friction Piles.—Mr. Vetter and many other writers on this subject assume the triangular friction distribution along a friction pile (Fig. 23(*a*)). This rather contradicts some existing experimental data and field observations. From several "energy-penetration curves" taken during pile-driving, it may be concluded that the friction resistance during driving is rather uniform along the pile,[35] although this statement by no means can be generalized or extended, unconditionally, to the case of static loading. However, assume that the triangular friction distribution as shown in Fig. 23(*a*) is correct. Suppose, furthermore, that instead of compression, a friction pile is subjected to tension. For instance, in Fig. 9 this would be the case with Pile 2 if the wind should blow somewhat stronger. The friction would be reversed in this case, and, to be consistent, one should imagine also the reversed friction distribution (Fig. 23(*b*)). A question arises as to whether the effective length in this case is two-thirds the length of the pile, one third, or some other value.

Wind Action.—In Fig. 9 it is necessary to consider also the reversed wind action (smaller, perhaps). This would modify the computed stresses somewhat.

Conclusion.—Mr. Vetter's paper is a valuable step in the direction toward which the design of pile foundations is being developed. This is an appreciable contribution to the rather meager English literature in this field. The writer, however, hopes for a trend toward simplifying the existing methods of design.

C. P. VETTER,[36] M. AM. SOC. C. E. (by letter).—The generous contributions which, in the form of discussions, have been made to the art and practice of the design of pile foundations, have been most gratifying. Much new light has been thrown on the various principles involved, and the writer wishes to express his appreciation.

Mr. Hill develops formulas for pile loads for the case in which all piles are parallel with each other. Apparently, it has been overlooked that under the assumption of the exterior load being resisted solely by axial pile reactions, such a foundation will be stable only if the resultant of the exterior loads is parallel with the piles. This may be seen directly from Equations (46*a*) and (46*b*) which by division yield:

$$\frac{H}{V} = \tan \alpha \qquad (91)$$

---

[35] *Proceedings,* Soil. Mech. Conf., Vol. 3 (1936), paper H-16.

[36] Engr., U. S. Bureau of Reclamation, Denver, Colo.

Such a pile foundation is only rarely encountered in practice, except in the case of vertical piles supporting a vertical load ($\alpha = 0$).

Mr. Hill extends the investigations to foundations having piles in opposite directions with equal (but opposite) batters. Equation (52) is believed to cover the case correctly. However, it is incorrect to apply this formula to the writer's numerical example, in that Mr. Hill seems to have neglected the vertical piles in the example. Presumably, this accounts for the deviation in numerical values of the pile loads given in Mr. Hill's tabulation following Equation (52).

Mr. Hill next discusses pile foundations for which the resultant of the exterior forces does not fall in the plane of symmetry of the pile group and is not even parallel with that plane. The writer wishes to warn prospective designers against taking too much for granted when considering pile foundations and loadings arbitrarily distributed in space. The problem is "tricky" and highly complex. It has been solved to perfection by C. Nökkentved[5] whose work should be consulted before important designs in this line are undertaken.

Mr. Hill further states that it is desirable that a foundation utilizing batter piles contain piles battered in opposition to each other. The writer agrees fully with this assertion. In fact, in the design of the pile foundations for Imperial Dam on the Colorado River (perhaps the most extensive pile-driving undertaking in the United States containing battered piles), all foundations had piles in opposite directions. Fig. 1(*a*) shows a typical bent of a part of Imperial Dam.

Professor Albert draws attention to the valuable contributions made by Swedish engineers, about thirty or more years ago, to current knowledge of the behavior of pile foundations. The writer gave proper reference in his paper to those early pioneers in the field. Mr. Albert prefers Hultin's graphical method for the determination of pile loads for the case of hinged piles, and the writer agrees that, for one thoroughly familiar with that method, results may possibly be obtained in less time by the use of that method than by the formulas given in the paper. The difficulty with Hultin's method, as with nearly all the older methods, is that, although the applications may be speedy after the method has been mastered, the method itself is so intricate that considerable time must be spent by the designer to familiarize himself with the subject or to "brush up" on it even if he has known it once. To most engineers the designs of pile foundations come only rarely, and it would seem of considerable importance that the principles used in such designs should be formulated so simply that actual numerical work may be undertaken with the least possible delay. The expert who does little besides designing pile foundations would do well, and possibly would save time, by studying some of the other works on the subject, as referred to in the paper. He should ascertain, however, that the method he proposes to utilize rests on a sound theoretical base. The references given by the writer and by Mr. Albert are believed to be reliable in this respect.

Mr. Niederhoff appears to be mostly concerned with defending the still widely employed practice of designing pile foundations which depend for the stability of the structure on lateral resistance of the upper layers of the foundation material. The writer is definitely of the opinion, and so stated in his paper, that if the upper layers are of such consistency that they may safely be relied upon for lateral resistance, piles are not needed and should not be used. The reason is that, in driving the piles, the original firmness of the upper layers of the soil is often destroyed and so is the soil's capacity for resisting lateral loads.

Mr. Niederhoff would seem, in places, to have misunderstood some of the points brought forth in the paper, possibly because of lack of clarity on the part of the writer. The statement is made that "His [the writer's] analysis also appears needlessly complicated and leads to values that are different from those obtained by the writer [Mr. Niederhoff] using only the resolution of forces into components that act upon the piles axial and normal to the axis." The writer maintains that an analysis is "needlessly complicated" only when the same result, or a result equally correct, may be obtained by some other analysis which is easier, less complicated, or more readily understood. That results, different from the writer's, are obtained by Mr. Niederhoff's analysis is not surprising, in that he satisfies the equilibrium conditions only, without paying any attention to deformations or displacements. The relationship between a pile's axial compression and its lateral displacement does not depend only on the pile's batter and the direction of the resultant. It depends most of all on the location of the resultant with respect to the top of the piles. The movement of the resultant laterally from one side of the elastic center to the other may reverse the direction of the lateral displacement of the pile heads and, as a result, reverse the direction of the lateral resistance. It was one of the main purposes of the paper to demonstrate this, possibly surprising, but nevertheless unquestionable, fact.

Mr. Niederhoff further objects to the writer's statement that "In many practical cases, such as bridge piers and gate piers in hydraulic structures, the error introduced by this assumption [that of hinged ends] is insignificant." The sentence that follows immediately in the paper may have been overlooked: "However, in some applications, such as pile bents for trestles, the error becomes of considerable magnitude."

Under "Pile Foundations Which Are Symmetrical About a Vertical Line: Comment," the writer stated:

> "* * * if, therefore, the piles, approximately, go through the same point the rotation for a given moment would be large. The assumption that the effect of restraint may safely be neglected does not hold for this case and the stability of the pier depends almost entirely on the restraint and the stiffness of the piles."

A group of vertical test piles, as referred to by Mr. Niederhoff, may be said to represent a pile bent at its worst, in that all piles intersect at the same point (infinity). That less deflection was found for the restrained test piles than for hinged ones would seem to bear out the writer's statement rather than to refute it.

In determining the depth at which the pile is restrained (necessary for the cases where restraint is important) Mr. Niederhoff prefers to follow the analysis by A. E. Cummings, M. Am. Soc. C. E.[23] The writer can see no objection to the use of Mr. Cummings' formulas as a guide. These formulas are based on very special assumptions, probably applicable to a test pile, but only applicable to a very limited extent to piles in an actual foundation. One of the assumptions in question is that the point of contraflexure occurs at half depth. This assumption applies neither to a test pile nor to a pile in an actual foundation. However, it affects the final result very little. Of greater consequence is Mr. Cummings' assumption that the tangent to the pile's deflection curve remains vertical at the top. Any structure supported on piles will rotate under load, unless the resultant of the exterior forces goes through the elastic center. The more nearly the piles intersect at a point, the greater the rotation will be, and the greater will be the error in assuming the tangent at the tops of the piles to be vertical. From a mathematical point of view, the analysis of the same problem by Y. L. Chang[37] is preferable to that of Mr. Cummings. Mr. Chang uses a somewhat different modulus of elasticity of the soil, but that might possibly be remedied.

Mr. Eremin suggests direct algebraic solution of the three simultaneous equilibrium equations. The method is direct but somewhat tedious and time-consuming in the case of many piles. Furthermore, the sign conventions become of primary importance since there is no direct check on the work as it progresses.

Mr. Feld submits a number of general statements regarding the behavior of piles under load. In every case he seems to conclude that the behavior of a pile foundation consisting of many piles is similar to the behavior of a single pile subject to a similar load. Such conclusions are not permissible. The case can best be illustrated by an example. Assume a batter pile, *A B*, acted upon by a horizontal force, *P* (Fig. 24). Mr. Feld uses exactly this case as an illustration. In order for the pile to be in equilibrium, at least two forces, *R* and *S*, are required. They must be produced by the resistance of the soil or, in some equivalent manner, by the stiffness and embedment of the pile. If the soil offers insufficient resistance to lateral displacement, or if the pile lacks stiffness or strength, the structure will fail. If, now, a second pile, *A C*, is provided, the lateral forces *R* and *S* are not required for equilibrium and no reliance need be placed on the lateral resistance of the soil or on the stiffness and flexural strength of the piles. All that is necessary is that the piles can sustain axial loads such as *Q* and *T*. That *T* is tension is of no particular importance; as a rule there are sufficient vertical forces also acting on the structure to counterbalance the tension. It is believed that this simple example presents the advantage of battered piles in the simplest possible manner and that it answers virtually all the questions raised by Mr. Feld.

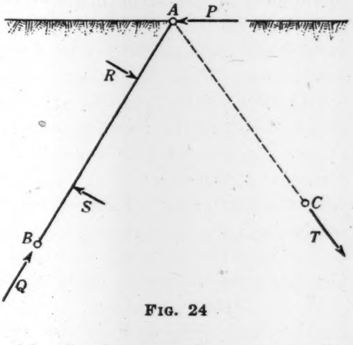

FIG. 24

---

[37] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 272.

Mr. Coan presents an example of a three-dimensional pile group analyzed by methods similar to the writer's. The results in this particular case seem to agree fairly well with model test results. However, as mentioned previously, great caution should be exercised in applying the writer's methods to spatial pile groups and loading conditions.

Professor Agatz presents a very ingenious method for direct determination of pressures in pile foundations consisting of piles in three different directions. His method is entirely algebraical, whereas the writer's method, in the general case, is partly algebraical and partly graphical. The theoretical background for both methods is, needless to say, the same. For the special case in which one of the three pile groups is vertical, complete formulas ready for use are presented. The only criticism the writer would venture in connection with this discussion is the use of numerical values instead of algebraical values for the ratio m ($|m|$) and the angles α ($|\alpha|$). As a general rule the writer believes this to be a dangerous practice. Sign errors constitute a surprisingly great proportion of the errors made in engineering calculations and, at times, such errors are very difficult to detect. For that reason the writer is in favor of definite sign conventions and strict adherence to them. As far as Professor Agatz' discussion is concerned, this is, of course, a minor matter. His equations, although complicated in appearance, are not as complicated in actual use as might be expected. In general, the writer prefers methods which present a little easier avenue of approach but, since Professor Agatz' method is primarily applicable to retaining walls and quay walls with considerable duplication, the designer can well afford to spend considerable time in becoming familiar with this special method.

Professor Krynine calls attention to the fact that the writer's method produces pressures on each pile but not settlements on the structure due to these pressures. This deficiency was recognized in the "Synopsis" of the paper, from which is quoted: "It is the subsoil that 'carries' the load, and consolidation of soft material below the piles will inevitably contribute its share to the settlement of the structure whether or not piles are used," and further, "It may be argued * * * in particular, that considerations from the point of view of soil mechanics have been neglected in favor of those of purely structural mechanics. This argument cannot be refuted in a general manner." It would be equally futile to attempt to refute Professor Krynine's argument. The purpose of the paper was restricted and was limited to the determination of pile stresses, and, in general, to the encouragement of the use of battered piles for structures subject to horizontal loads. It did not deal, primarily, with the settlement of structures, and to attempt to predict such settlements solely from the pile stresses would obviously be erroneous. Settlements due to causes other than the elastic deformations of the piles will probably affect the pile stresses, particularly in cases where the restraint of the piles is important. Hence, contrary to the apparent opinion of some of the discussers, the methods proposed by the writer are best suited for pile foundations in which the restraint of the piles is of minor importance; that is, large bridge piers and piers for hydraulic structures. In such structures the pile stresses are likely to be least affected by secondary earth movements.

Only one other of the points raised by Professor Krynine needs to be discussed further; namely, that of the distribution along the pile's axis of the frictional forces. This question was also raised by Mr. Niederhoff. The proposed use of the triangular distribution has a very simple explanation. Assume that the coefficient of friction between the pile and the soil is constant and independent of the normal pressures and of the rate and magnitude of the relative movements. The coefficient of friction between solid substances is generally assumed to have just those characteristics. The frictional resistance to the movement of the pile would thus be directly proportional to the lateral earth pressure which, again, is usually assumed to be rectilinearly increasing with depth. As a result, the friction per unit area would increase rectilinearly with depth and, if the pile is cylindrical or prismatic, the friction per unit length of pile would also increase rectilinearly with depth. In the case of a tension pile, conditions would be exactly the same except that the normal earth pressure, according to the familiar Coulomb-Poncelet earth-pressure theory, is less in the case of a vertically upward movement of the pile than it is for a vertically downward movement. The writer does not agree with Professor Krynine that a consistent conclusion would be that, in the case of a tension pile, the frictional force would be maximum at the top and zero at the tip of the pile.

FOREWORD

By George E. Barnes,[1] M. Am. Soc. C. E.

Since 1933 the construction of sanitary engineering projects has been financed largely by Federal funds allocated as loans or grants-in-aid. Federal funding agencies act in part as co-ordinating agencies also, in reviewing studies and plans for various types of projects proposed for individual population centers and local areas. In the Ohio Basin as elsewhere, such review has made more apparent than ever the desirability of more comprehensive planning for the region as a whole, as the basis for a long-range policy on conservation and proper utilization of water resources.

The Ohio Basin, from the standpoint of size, natural wealth, and population supported, is one of the most important in the United States; and it seems appropriate at the present time to focus technical and lay interest on its peculiar sanitation problems. With this object in mind, the Cleveland Section of the Society appointed a Special Committee to work in co-operation with the Sanitary Engineering Division and to organize a Symposium on Stream Pollution in the Ohio Basin. The Committee included the writer as Chairman, and George B. Gascoigne, Rollin F. MacDowell, and George B. Sowers, Members, Am. Soc. C. E. The Committee was of the opinion that, although there may be interesting and comparatively unexplored problems in sanitary engineering, particularly in the field of industrial wastes treatment, nevertheless questions of design or treatment processes might properly be subordinated in this Symposium to an appraisal of the critical problems now existing in the water-shed, the outlook for co-ordinated planning, and the procedure for initiating and enabling sanitation improvements. Emphasis in the following papers is directed toward this end.

Mr. Streeter's paper describes methods for surveying the extent of pollution and gives the results of such a survey on the Ohio River, together with suggestions for minimum standards for river condition. Mr. Ryder's paper, discussing the operation of the Pymatuning Reservoir, shows that in certain cases it may be at least as valuable to regulate dry-season flow for dilution purposes as to invest in sewage plants complete with secondary treatment. Mr. Stevenson's paper is devoted to the extraordinary duties carried by the Pennsylvania Department of Health in time of flood, and indicates from experience many factors that must be considered in the design of sanitary engineering projects and in the organization of service agencies, if these are to function during emergencies. Mr. Tisdale's paper sets forth an excellent picture of sanitary conditions in the Ohio Basin as a whole, and is supplemented with papers by Mr. Davis on the problems at Pittsburgh, Pa., and by Mr. Root on those at Cincinnati, Ohio, the two major metropolitan centers of the Ohio Basin. The concluding paper, by Mr. Wolman, is concerned with the medium through which comprehensive planning and adequate financing may be secured. The discussions of this Symposium will be no less important than the topic papers themselves, in presenting a balanced understanding of sanitation problems in the Ohio Basin.

SURVEYS FOR STREAM POLLUTION CONTROL

BY HAROLD W. STREETER,[2] M. AM. SOC. C. E.

SYNOPSIS

The effective control of stream pollution, when viewed as an engineering problem, entails not only the design of sewage and industrial wastes treatment plants, but also the formulation of comprehensive plans for restoring and maintaining entire river systems in proper condition for various water uses, avoiding the wastefulness of over-correction in some areas and the ineffectiveness of under-correction in other areas. The base data for such plans are obtainable from field and laboratory surveys of a river and its tributary drainage area.

Field surveys of this character will embrace all major sources of pollution; vital statistics of water-borne diseases in various parts of the water-shed; the extent and kind of water uses in different areas; hydrometric data for the river and its main tributaries; and information bearing on time intervals of flow in the river between various sources of pollution. Laboratory surveys will include data on the quality of stream waters at water intakes and below sources of pollution; on progressive changes in "oxygen balance" in more highly polluted river zones, and in special cases, on turbidity, alkalinity or acidity, hardness, and certain metals detrimental to the quality of the stream waters and their different uses. Biological data will embrace major groups of pollutional and non-pollutional organisms, both in the stream proper and in the bottom sediments, and likewise organisms detrimental to water supplies.

Where pollution control is designed so as to utilize the natural purification capacity of a waterway, limiting conditions of pollution should be fixed tentatively for various water uses, as the basis of interpreting the laboratory findings. Examples of such criteria are given with respect to water supply sources, nuisance prevention, and maintenance of normal aquatic life in stream waters.

Considering the Ohio River System as presenting a fairly representative large-scale problem of stream pollution control, a brief account is given of the various surveys of this river made during recent years and the main conclusions derived from them. To illustrate the application of laboratory survey data collected in this river, results are shown of an estimate of the relative responsibility of sewered population groups draining into various zones of the river for conditions of bacterial pollution at several water intakes. These results indicate that except in the winter, when the effects of natural purification are at a minimum, the major portion of sewage bacteria surviving in the river at each intake appears to be traceable to population groups draining

---

[2] Senior San. Engr., U. S. Public Health Service, Cincinnati, Ohio.

into the river, either directly or indirectly, within about 200 miles up stream from that point. In winter, the effect of more distant population groups is apparent. It also is shown that acid conditions in the Ohio River and its tributaries above Wheeling, W. Va., exercise a powerful repressive influence on bacterial pollution originating in this part of the river system. With the amelioration of the acid conditions resulting from mine-sealing and other corrective measures in progress, extensive treatment of the sewage from populations now draining into this zone of the river will be necessary, in order to avoid serious overburdening of water purification plants with excessive bacterial pollution originating in sewage. Study needs to be given to the degrees and methods of sewage and industrial wastes treatment best adapted to meeting water use requirements in different parts of this river system, and also to the probable effects of large volumes of treated effluents on the stream waters and their several uses.

With the growth of public interest in stream pollution as a nation-wide problem, legislators and sanitarians have been impelled to extend their views of the subject far beyond local horizons. Until recently the sole objective of "stream cleaning" was usually the removal of local "sore spots." Little, if any, thought was given to more remote down-stream conditions, which were left to those concerned to deal with as best they could. However, it is now becoming more generally recognized that river pollution, like floods, is no respecter of local boundaries, and that if control measures are to be permanently effective they must comprehend entire drainage areas, or, at least, those portions of them in which sewage and industrial wastes impose a definite burden on streams.

This general broadening of viewpoint with respect to stream pollution and its control has brought with it a marked change in the nature and complexity of the engineering problems to be solved, not so much as regards the actual treatment of wastes, as regards the formulation of workable plans for pollution control. Such plans must be designed to restore and maintain complete river systems in proper condition for various water uses, and must avoid, as far as possible, the wastefulness of over-correction in some areas and the ineffectiveness of under-correction in other areas. It is with this latter phase of the problem and more especially with the surveys and other studies essential to a well-planned system of river-pollution control that this paper is concerned.

In a broad sense, a certain engineering analogy may be said to exist between a river system under effective pollution control and a well-planned structure, such as a bridge, which must be designed so that the maximum stress imposed on every individual member does not exceed its safe working strength. In such a river system, for example, the degree of pollution, both of the main stream and of the various tributaries, must be limited to a maximum consistent with the suitability of those streams for specified water uses, and in no case may it exceed their respective capacities for dilution and natural purification.

The limitation in pollution imposed by water use may be likened to the safe working load on a structure, and the limitation imposed by dilution and self-purification corresponds to the ultimate breaking load. A well-marked distinction is to be noted, however, between ordinary structural design and stream-pollution control in that, in the first instance, the load is predetermined and the strength or capacity of the structural members can be adjusted to support such a load, whereas, in the second instance, the limiting strength of the structure is predetermined (by the capacity for dilution and natural purification) and the load, or degree of pollution, must be adjusted accordingly.

From the foregoing analogy, it is fairly evident that as it is necessary to make a thorough study of loadings and allowable stresses in designing an ordinary engineering structure, it is equally essential in planning stream-pollution control, to make a similarly careful and detailed study of the nature and extent of the pollution of a river system and also its capacity for dilution and natural purification. The basic data for such a study are usually obtained through field and laboratory surveys of the river and its drainage area, extending over a sufficiently long time to reveal the normal seasonal fluctuations in temperature, run-off, velocities, and time intervals of flow in the streams, and other seasonal variables.

General Survey Methods

A survey of sources of pollution will include rural, urban, and sewered populations, and their trends of growth or change in different parts of the river system. It also will include waste-producing industries, listing them according to character, location, and the strength and volume of wastes produced in relation to amounts of manufactured products. All water intakes along the main stream and its major tributaries should be located. In the vicinity of the larger sewered communities, all the more important sewer outlets should also be located, and detailed information should be obtained in each case on the size of the contributing population, the volume and strength of the sewage, and the nature and extent of sewage treatment. Such a survey, which would entail visiting practically every sewered community on the water-shed, might well be supplemented by collecting available statistics on the prevalence of water-borne disease in each community (particularly typhoid fever and gastro-enteritis) and on the quality of the public and private water supplies. Drainage areas of the main stream and its various tributaries should be mapped and determined by careful planimeter measurements. These several items of data would fall under the ordinary field survey, to which the hydrometric and laboratory surveys would be supplementary.

The main objective of the hydrometric survey is to obtain detailed information as to the amount of dilution water available at different points in the river system, and its variation from day to day, or week to week, throughout the period covered by the laboratory survey. Collection of these data involves the establishment of gaging stations in the main stream and on all important tributaries, the systematic collection of gage-height records, and a sufficient number of discharge measurements at each station to define accurate rating curves. Where data are available bearing on cross-sectional and surface areas of the main stream at different stages of flow, such data are of value in estimating mean velocities and time intervals of flow at these various stages. Although usually less important, similar data for some of the major tributaries may be very useful in estimating periods of flow concentration for these tributary drainage areas. Where such data are not obtainable, velocities and time intervals of flow may be estimated from float measurements or, in very small streams, through the use of strong dyes.

The purpose of the laboratory survey is to show actual conditions of pollution, with their seasonal and other variations, in the main stream and major tributaries, having in mind maximum and minimum as well as average conditions at various times and the periods of duration of the several conditions observed. This survey should be designed to show the quality of water above and below main sources of pollution and dilution (tributaries) and also the extent of natural purification occurring in longer stretches of the river comparatively free from the disturbing influence of pollution or dilution. Particular attention should be given to the quality of water at water-supply intakes and at points in the immediate vicinity of major sources of pollution, where conditions are more likely to be unfavorable to recreational uses of the stream and where the demand for such uses is ordinarily more widespread.

For purposes of sampling, fixed points in the stream at known range line intersections are preferable to random stations. In the wider stretches of channel, three points on each cross-section may be selected and river samples collected, ordinarily at mid-depth, after checking several times the variations in river-water composition as between surface, mid-depth, and bottom. Under usual circumstances, the quality of water in a stream varies more widely at a given time in a horizontal direction on a cross-section than it does vertically at any point in such a section, although where marked sludge deposits are present, exceptions to this rule may be noted.

The number and character of laboratory determinations made in connection with a survey may vary widely with the size and complexity of the problem. However, for ordinary stream-pollution control, certain minimum requirements should be met. A detailed study should be made of the numbers of sewage bacteria (the *coli-aerogenes* group) and of their variations from day to day, or week to week, at different points in the main river and tributaries, particularly at sources of public water supplies and in the local areas affecting them. These data preferably should be supplemented by parallel observations of bacterial plate counts at the same points and in the same samples, in order to provide a check on the trends of the *coli-aerogenes* observations. The methods used in these and other laboratory determinations should follow the standard procedures described by the American Public Health Association.

In addition to the bacteriological tests, which are the most sensitive indices of significant changes in the degree of pollution of a river, systematic observations should be made of the dissolved oxygen and bio-chemical oxygen demand (B.O.D.) of the stream water at every major sampling station, in order that progressive changes in the "oxygen balance" (that is, the relation of available oxygen to oxygen demand) may be measured. The oxygen balance serves as an index of the adequacy of dilution and natural purification to dispose of more immediate pollution and also as a record of the fitness of the stream for normal aquatic life. The river water temperature should always be recorded at the time of collecting each dissolved oxygen sample, in order to provide a basis for estimating the degree of oxygen saturation, which varies with the temperature. The B.O.D. test as now made ordinarily is carried out by incubating sealed samples of the river water (undiluted, as far as possible) at a temperature of 20° C for 5 days, and measuring the loss of dissolved oxygen by the sample under these standardized conditions. Under some conditions, such as of heavy pollution or sludge deposits, B.O.D. determinations on identical samples, with incubation periods of 1, 5, 10, and 20 days, may be desirable occasionally in order to check the course of the oxidation curve through its first or carbonaceous stage. In other cases, notably where evidences of nitrification in the river are apparent, extension of the test period to 40 days may be desirable, in order to show the course of oxidation through both primary and secondary (nitrification) phases.

The addition of other laboratory tests to the routine schedule of the survey will depend largely on circumstances and on the facilities available at field laboratories. As indices of advanced oxidation in a river, the determinations of nitrite and nitrate are essential, as they show the final state of the oxygen used up in the stabilization of nitrogeneous organic matter. Determinations of turbidity and alkalinity are useful in measuring, respectively, the effects of sedimentation and of dilution in the river, the latter mainly through tributaries.

Certain other laboratory tests may be of value where special conditions or requirements are to be met. If the hardness or incrustant content of a river is an object of special interest, these determinations, together with those of calcium and magnesium, should be made regularly. Occasionally, the presence or absence of phenols in rivers from which water supplies are taken may be an important consideration. Similarly, iron and manganese are frequently matters of concern. In the streams of New England and the Southeastern States, the presence of dissolved coloring matter is often significant. In some rivers of the Western States draining lead and copper mining regions, the search for quantitative evidence of these toxic metals may be a matter of predominating importance in a laboratory survey. In every particular case, due consideration must be given to the uses made of the river water and to the presence of undesirable substances in the water. This applies particularly to the presence of substances originating in certain industrial wastes. As indices of ordinary sewage pollution, the bacterial and oxygen balance determinations are of primary importance.

The third main division of the laboratory survey is that which has to do with the biology of a river. In this connection it is not essential to stream-pollution control that an extensive or detailed biological survey of a river system be undertaken, although it is highly desirable that a sufficiently thorough examination be made of the supernatant stream and also of the bottom deposits to establish a clear record of the relative prevalence of pollutional and of non-pollutional organisms in different river zones. As these biological forms are an essential link in the chain of natural purification and as they doubtless will undergo marked changes in kind and relative numbers following the institution of sewage and industrial waste treatment, it is particularly important that these changes be recorded as a significant portion of the history of a river during and following the period of active stream sanitation measures. A fairly thorough biological survey before these measures are instituted and another after they have been completed will be well worth the time and expense required. In some instances, it will be advisable to maintain a more or less continuous check on biological conditions in a stream below major sources of pollution during the progress of initial corrective measures, in order to reveal any marked changes occurring in the balance of aquatic life and, where water supplies are involved, to furnish evidence of any tendencies toward the development of filter-clogging or taste- and odor-producing organisms which may impose an additional burden on water purification systems.

CRITERIA FOR PERMISSIBLE LIMITS OF POLLUTION

Although field and laboratory surveys will show the river zones in which conditions are either definitely satisfactory or otherwise for various water uses, they usually fail to reveal the limiting boundaries which lie between these two conditions; that is, in the rare instances in which these boundary conditions may prevail, the indications with respect to suitability or unsuitability for various water uses may be somewhat indefinite. If full utilization is to be made of the dilution and natural purification capacities of a given river system in undertaking a systematic program of stream pollution control, it is essential that some definite limiting criterion with respect to allowable density of pollution be adopted, tentatively at least, in order to provide a guide-post for correctional measures.

In general, the particular criterion, or set of criteria, adopted will depend on the more important uses made of a river in a particular zone, such as water supply, recreation, commercial fishing, industrial requirements, etc. In general, the suitability of a river as the source of public water supply is the predominant interest to be served. In many river zones from which water supplies are not ordinarily taken (as in the zones immediately below sewered communities), the rapidly growing pressure for enlarged recreational uses has brought to the forefront many problems of local sanitation affecting the use of streams for boating, fishing, camping, and even bathing. In relatively clean rivers now devoted principally to recreational uses, the question of preventing future impairment for such uses is a vital one in many States, affecting not only the interests of riparian dwellers, but also those of an increasing number of people from all parts of the country, whose annual migrations to these water centers in quest of rest and change are rapidly assuming the proportions of a national movement.

The results of an extensive study carried out by the United States Public Health Service in 1923–1927, led to the conclusion that where the sewage pollution of sources of public water supplies does not exceed that which is represented by a *coli-aerogenes* bacterial number of 5 000 per 100 cu cm as a rounded figure, purified water supplies conforming in quality to the primary requirements of the Treasury Department drinking water standard should be consistently attainable with the aid of efficient modern water purification systems. This figure would provide a fairly simple criterion for limiting river or lake pollution at intakes from which public water supplies are withdrawn. If taken as a yearly average, this figure would be scaled downward to some extent, depending on the character and variability of pollution at the particular water source considered, in order to ensure conformance of the purified water supply to both primary and secondary requirements of the Treasury Department *B. coli* standard. Thus, it has been noted by the writer in a previous paper,[3] that an annual average *coli-aerogenes* index of about 3 000 per 100 cu cm would represent a safer upper limit of pollution for sources of water supply located along the Ohio River, and probably also along its major tributaries.

It is of interest to note in Table 1 the yearly average numbers of *coli-aerogenes* bacteria recorded during the 10-yr period, 1926–1935, in the raw water supplies of ten municipal filtration plants along the Ohio River.[4] If judged by the aforementioned criterion, the raw waters at East Liverpool, Marietta, Ashland, Ironton, Portsmouth, and Cincinnati, in Ohio, are shown to be definitely over-polluted, and the water at Steubenville, Ohio, has reached approximately the safe upper limit of average pollution. During the extreme drought year of 1930, conditions at all the cities named are shown to have been considerably aggravated, except at Cincinnati, where they were improved to a marked extent, owing to the effects of long storage and sedimentation in the relatively unpolluted and canalized 100-mile stretch of river above this point. Consistently, gross over-pollution is indicated at Ashland and Ironton, where the effects of heavy local pollution in zones immediately up stream are particularly manifest.

In setting the permissible limits of pollution in river zones from which public water supplies are not taken, the problem is largely one of fixing conditions satisfactory for maintaining freedom from local nuisance, supporting normal aquatic life, and, in some instances, keeping certain areas fit for bathing and camping purposes. For prevention of local nuisances, it is primarily desirable to eliminate organic sludge deposits, whether they originate in sewage or in certain kinds of industrial wastes. It also is necessary to maintain dissolved oxygen in the stream proper at all times, to prevent septic action with ensuing odors. In order to support normal aquatic life, which has a vital function in maintaining natural purification and in the general fitness of waters for recreational uses, a minimum oxygen content sufficient to support respiration in the higher aquatic animals, notably fish, is necessary. Some authorities recommend an oxygen minimum ranging from 2.5 to 5 ppm, with the additional requirement that the reserve oxygen supply present in a stream should always exceed the bio-chemical oxygen demand. A fair average for this dissolved oxygen minimum, under present general requirements, appears to be about 4 ppm. Organic sludge deposits should be eliminated not only because they interfere with the normal spawning process of fish, but also because these deposits impose a heavy oxygen demand on the overlying stream.

---

[3] "Limiting Standards of Bacterial Quality for Sources of Purified Water Supplies," by Harold W. Streeter, *Journal*, Am. Water Works Assoc., Vol. 27, September, 1935, pp. 1110–1119.

[4] For convenient access to these data, the writer is indebted to H. R. Crohurst, Senior Sanitary Engineer of the U. S. Public Health Service.

As the prevention of nuisance and the maintenance of normal aquatic life in streams are closely inter-related, it would appear reasonable to assume that a single requirement sufficient to meet both conditions should be imposed in all river zones where the provision of recreational facilities for the general public and the preservation of other "amenities," such as the use of adjoining shore areas for residential purposes, may be involved. With the exception of bathing, which would require a relatively high bacterial standard of water quality, the simple requirement that the dissolved oxygen content should never be less than the oxygen demand, nor less than a minimum of about 4 ppm, should be sufficient to maintain favorable conditions, with the added proviso that all organic sludge deposits should be eliminated from the stream channel. It also may be noted in this connection that a stream conforming in all zones to a reasonable requirement for protection of sources of water supplies, such as that stated previously in this paper, would be brought more or less automatically within a favorable oxygen balance requirement such as the one just suggested. Neither of these two requirements would be adequately rigid, however, to meet even the more lenient of the various bathing water standards now being followed in different parts of the United States. It is, indeed, a debatable question as to whether under present circumstances the greatly added expense of restoring a highly polluted river to a condition safe for bathing throughout its entire course would be economically justified, although the institution of general corrective measures designed to protect sources of public water supply probably would result in the reclamation for these purposes of some areas remote from immediate sources of pollution.

From the foregoing discussion it thus appears that, in general, limiting pollution requirements may be fairly simple, consisting of the following: (1) Fixing maximum permissible numbers of *coli-aerogenes* bacteria in stream waters at public water supply intakes; (2) setting minimum oxygen and oxygen balance criteria in local areas below sources of pollution; and (3) working toward the practical elimination of all sludge deposits originating in sewage and in putrescible industrial wastes. In addition to these requirements, there would be certain special ones, applicable only in certain cases, such as the elimination of toxic, highly acid or alkaline, and taste- and odor-producing substances, not ordinarily removable by water purification processes. In the

Ohio River, acid wastes from mines and steel mills and phenolic wastes from by-product coke plants have presented major problems in this respect, although systematic efforts are being made to eliminate these sources of pollution, through mine-sealing operations and the diversion of steel and coke wastes at individual plants.

SURVEYS OF THE OHIO RIVER

Owing to the size and importance of the Ohio River System and to the fact that it constitutes both a drainage channel and a source of public water supply for a large population, this river and its main tributaries have long been considered as presenting one of the most complex and difficult problems of stream pollution control in the entire country. Recognizing this fact, the U. S. Public Health Service, under authority of an Act of Congress passed in 1912, conducted in the years 1914–1916 a survey of pollution along the Ohio constituting probably the most detailed and comprehensive study of its kind ever undertaken, either in the United States or abroad. In connection with this investigation, a thorough hydrometric and laboratory survey was made at a series of sampling stations covering nearly the entire course of the river from Pittsburgh, Pa., to its mouth. During the summers of 1914 and 1915, a detailed sanitary survey was made of every incorporated community of more than 8 000 population in the entire water-shed.

The results of this survey, which were published in three reports,[5] revealed the main sources of pollution of the river, including both sewage and industrial wastes, the normal ranges of flow in the main stream and major tributaries, and certain definite zones of retrogression and of recovery in the density of pollution of the river. Zones of retrogression included the densely populated Pittsburgh-Wheeling Section, and stretches immediately below Cincinnati and Louisville. Zones of recovery, owing to dilution and natural purification, occur below Wheeling and in the long and relatively unpolluted stretches extending from Portsmouth to Cincinnati, from Cincinnati to Louisville, and from Louisville to the mouth of the river. The effects of acid pollution, derived from coal-mine and acid-iron wastes, were clearly apparent in the Pittsburgh-Wheeling Section, in stimulating precipitation of suspended material in the river and in exerting a well-marked bactericidal effect on sewage and other wastes discharged in that section.

A later survey of municipal water purification systems along the Ohio River, which was carried out by the Public Health Service in 1923 and 1924, indicated that the most highly polluted zone of the river from which public water supplies are taken extends from a point below Huntington to one just above Portsmouth, a distance of about 35 miles, in which the effects of sewage from Huntington are augmented by those of the combined wastes of Ashland and Ironton. Next in importance from this standpoint was the zone extending from below the mouth of the Beaver River, about 25 miles below Pittsburgh, to Steubenville, 35 miles farther down stream. In this section are the water intakes of East Liverpool and Steubenville, where increasing difficulties in producing satisfactory purified water supplies have been experienced during recent years.

---

[5] *Public Health Bulletins Nos. 131, 143,* and *146,* U. S. Public Health Service, Washington, D. C.

In general, this water purification survey[6] indicated that: (1) Water filtration plants in the Huntington-Portsmouth Zone are clearly over-burdened by sewage pollution; (2) the plants at East Liverpool and Steubenville are likewise over-burdened during considerable periods and also have difficulty at all times in producing palatable effluents; and (3) those at Cincinnati and Louisville, although not seriously over-burdened, are in a marginal zone between safety and danger in this respect. Without the aid of effective and continuous chlorination, no water filtration plant located on the Ohio River, or on a large number of its major tributaries, would be able, under present conditions of pollution, to produce effluents safe for human consumption or domestic use.

In the 15-yr interval between 1915 and 1930, the completion of Government dams in the Ohio River brought that river to a state of full canalization during periods of low water. In order to ascertain the effects of this canalization, and of the natural increase in tributary population, on the state of pollution of the river, a re-survey of its mid-section (from above Cincinnati to below Louisville) was carried out in 1930–1931 by the Public Health Service.[7] This survey showed that with full canalization in effect during summer periods of low water, conditions at water intakes located in or immediately below long and unpolluted stretches of the river were improved, but that during periods of freshets, when accumulated deposits of sludge are flushed out of the channel, conditions were markedly worse than would have been expected under continuous open-channel flow. In river stretches extending below large centers of pollution, the main effect of canalization during low-water periods appeared to have been to move the critical zone of pollution-density up stream toward these centers, with a corresponding temporary improvement in conditions farther down stream.

In addition to the foregoing studies, several more localized pollution surveys confined to limited areas have been made in the Upper Ohio River, including a survey of the Weirton-Wheeling Section by the West Virginia Department of Health, in July and August, 1932; a survey of the Ohio, Allegheny, and Monongahela Rivers in and near the Pittsburgh District, by the Pennsylvania Department of Health (September, 1932, to February, 1933); and a more recent study in the Pittsburgh District, in 1935, known as the Metropolitan Main Drainage Survey.

As a basis of stream-pollution control, the data now available on the main river probably need extension in a few respects, and more detailed information is required on conditions in some of the more highly polluted tributaries, notably those draining into the upper section of the Ohio River above Cincinnati. In general, the following supplementary data would appear to be desirable:

(1) Revised estimates of total, urban, and sewered populations in various sub-divisions of the water-shed, brought up to date from the 1930 Census.

(2) Complete data on industrial wastes and on the present extent of sewage and industrial waste treatment.

(3) Revised information on present velocities and time intervals of flow in the river under low-water conditions with full canalization in effect.

---

[6] *Public Health Bulletin No. 172*, U. S. Public Health Service, Washington, D. C.

[7] *Loc. cit., No. 204*, U. S. Public Health Service, 1933.

(4) Extension of local main drainage surveys along lines similar to those of the recent Pittsburgh survey.

(5) A complete survey of water surface areas and rates of atmospheric re-aeration in zones of the river below major sources of pollution and, more generally, in sections of the river in which the maintenance of a favorable oxygen balance is an important objective.

(6) A survey of the location, extent, and nature of organic sludge deposits in the river, particularly during periods of canalization.

The practical significance of Items (5) and (6) has been emphasized by the results of studies[8] made by the Public Health Service at its stream pollution research station at Cincinnati. It has been found that in stream waters polluted by sewage, or by underlying deposits of sewage sludge, the surface rate of atmospheric re-aeration (which is the most important limiting factor in determining the speed of natural purification) may be retarded measurably with sewage concentrations as low as 2 to 5%, which is within the range of local pollution density in many streams, including certain sections of the Ohio River. With higher concentrations of sewage (up to 25%), this retardation may reach 60% or more of the normal re-aeration rate. It also has been ascertained from the study that this retarding effect tends to be diminished by natural purification and also by artificial oxidation processes of sewage treatment, although it apparently is unmodified by simple chlorination. It has also been observed that the rate of oxidation of sewage sludge deposits under stream-flow conditions tends to be considerably lower than the corresponding rate for sewage matters in free suspension and solution.

The practical inference to be drawn from these results is that sewage pollution imposes a double burden on streams, by increasing the oxygen demand and retarding natural oxygen recovery; and that it is necessary to take into account both these elements in estimating the benefits to be attained by sewage and industrial-waste treatment in a particular river zone. The studies also point to the importance of sludge deposits as a burden on polluted streams and to the necessity of locating and eliminating these deposits at their sources, if a given stream is to be restored to a healthy condition.

Application of Survey Data

The applications made of survey data in formulating practical measures of stream-pollution control are so numerous and varied that any comprehensive discussion of them would extend beyond the limited scope of this paper. For the present purpose, a single example will serve to illustrate how such data may be utilized in studying a specific problem.

One of the important problems connected with the pollution of a large river system in which adequate protection must be given primarily to sources of public water supply, is the relative effects which various population groups discharging sewage into the river, either directly or indirectly, may have on pollution at down-stream points, notably those at which public water supplies are taken. In a river of the size and length of the Ohio, dilution and natural purification are dominant factors in the situation, although in this particular river the effect of acidity, chiefly from mine wastes, on conditions both in the upper river and at points down stream, is an important element to be considered.

---

[8] Publication pending in *Sewage Works Journal.*

From the *B. coli* data given in Table 1, it is apparent that the density of bacterial pollution of the Ohio varies widely at different water intakes and that all the factors previously noted exert their influence. The data reveal little, except by inference, as to the relative responsibility of various sources of pollution for the conditions observed.

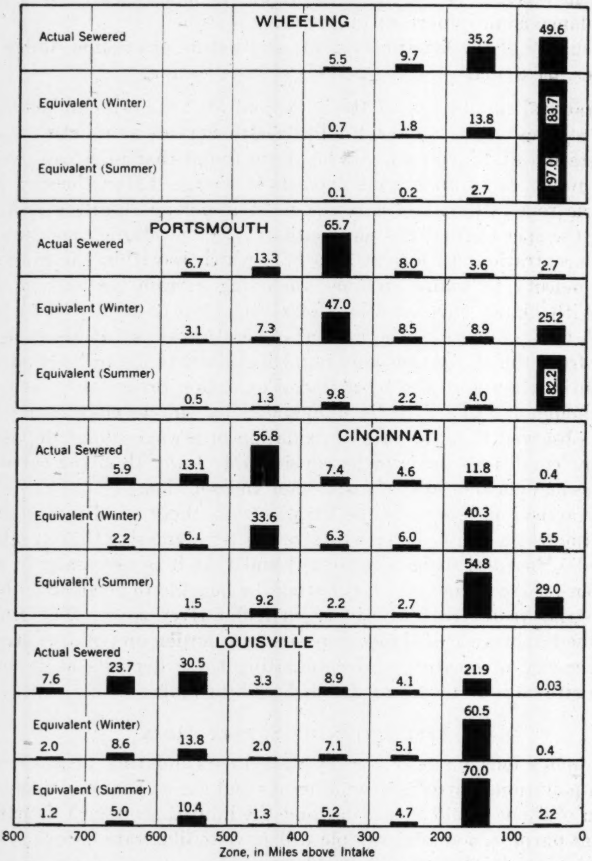

Fig. 1.—Percentage Contribution of Up-Stream Population Groups to Bacterial Pollution at Four Water-Supply Intakes on the Ohio River

In a paper given before the Society in 1927,[9] a method was described for determining the extent of such relative responsibility by "stepping down" the polluting effect of population groups located in successive river zones above a certain point in accordance with the observed mean time of flow from each zone to that point, and assuming that the reduction in the effect of each group would be measured along a time curve (varying with season and temperature) showing the rate of bacterial decrease in the river below sources of pollution. Curves of this kind were derived from extensive observations made by the U. S. Public Health Service in its 1914–1916 survey of the Ohio River, and were included in the paper mentioned.[9] By summing up the "stepped-down" population equivalents for all the river zones above a given point, a total equivalent population figure is obtained representing the population which, if it discharged sewage immediately above the point, would produce the same pollution effect as the actual population distributed in the various successive zones.

---

[9] "Sewage-Polluted Surface Waters as a Source of Water Supply," by H. W. Streeter. (Presented at the Spring Meeting of the Society, Asheville, N. C., April 20, 1927. Not published by the Society.) Public Health Reports, June 15, 1928, pp. 1498–1522; Reprint No. 1232, U. S. Public Health Service.

In the present instance, a study has been made of the relative effects of sewered population groups draining into the river in successive 100-mile zones above the intakes at Wheeling, Portsmouth, Cincinnati, and Louisville. In Fig. 1 are shown the estimated actual sewered populations (as of 1930) in successive zones above each intake, expressed as percentages of the total sewered population above the intake. Directly beneath them are shown, for average winter and summer conditions, the relative effects of these population groups at each intake, expressed as percentages of the total "stepped-down" population-equivalent originating in the successive zones.

It will be noted that at Wheeling, a large proportion of the bacterial pollution is indicated as being due to the effect of the sewered population, aggregating about one-half the total above this point, draining into the first 100-mile zone up stream. Within this zone is included the population of the Pittsburgh District and the dense population draining into the Lower Beaver River. Passing down stream, the effect of this large population group is apparent at Portsmouth (300 to 400 miles above), at Cincinnati (400 to 500 miles), and at Louisville (500 to 700 miles), although in progressively diminishing proportion. At these three lower intakes, however, the predominant factor in the pollution of the river is shown to be the sewered population located within a river distance of about 200 miles up stream. Above Portsmouth and Cincinnati, the actual sizes of these groups are relatively small in comparison to those of the total populations draining above these points, being only 6.3% of the total at Portsmouth, and 12.2% at Cincinnati. Above Louisville, however, the effect of the Cincinnati District, located in the 100 to 200-mile zone up stream, is clearly apparent in the percentage of the total actual population in this zone (21.9%) and in its very large relative effect (60.5% of the total in winter and 70.0% in summer).

In order to obtain a rough idea as to the extent to which acid conditions in the Upper Ohio River above Wheeling might tend to modify the relative pollutional effects shown in Fig. 1, the same calculations were repeated, assuming reduction factors for all sewered population groups draining into the river above Wheeling. The factors assumed were based on the comparative results of measurements made by the Public Health Service at Pittsburgh and Wheeling in 1914, and at Cincinnati, Louisville, Peoria, Ill., and Chicago, Ill., in 1914–1916 and 1921–1922.[10] These measurements showed that because of acid conditions in the river, the measured effect of sewage from Pittsburgh and Wheeling on the *B. coli* content of the river was much less in proportion to contributing population than at the other cities noted, which were not thus affected and were considered as normal in this respect. The per capita contribution of sewage bacteria to the river in zones above Wheeling averaged 25.6% of the normal under winter conditions and 0.9% under summer conditions, these percentages being the actual ratios of the measured contribution at Pittsburgh to the mean of those observed at Cincinnati, Louisville, Peoria, and Chicago. In Fig. 2 are shown the results of this recalculation in comparison with those first illustrated in Fig. 1.

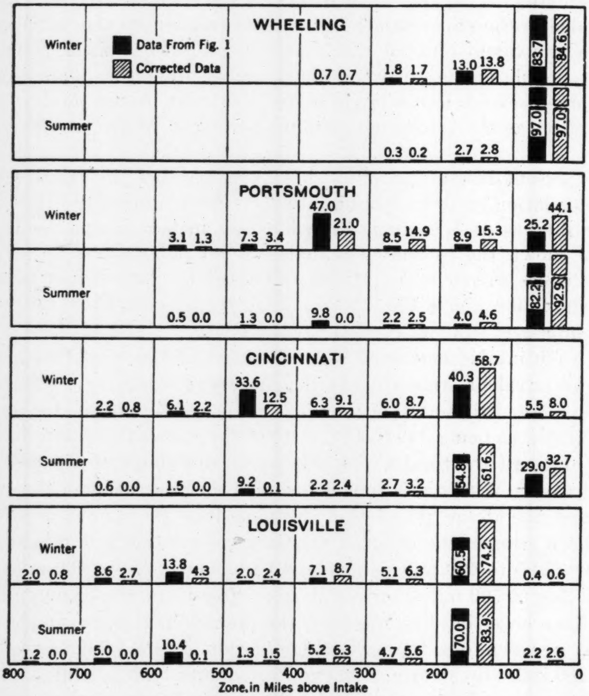

FIG. 2.—COMPARISON OF DATA IN FIG. 1 WITH CORRESPONDING DATA CORRECTED FOR EFFECT OF ACID WASTES DISCHARGED ABOVE WHEELING, W. VA.

Although the actual density of pollution in the river in terms of equivalent sewage-contributing population, was considerably lower when allowance was made for the influence of acidity above Wheeling, the relative effects of the several population groups were not modified to any large extent, except for a measurable reduction in the effect of the Pittsburgh-Wheeling Zone population group at Portsmouth, Cincinnati, and Louisville, as indicated in Fig. 2 by the smaller percentage of the total pollution originating in the 300 to 400-mile zone above Portsmouth, the 400 to 500-mile zone above Cincinnati, and the 500 to 700-mile zone above Louisville.

In order to show quantitatively the estimated reductions in the total pollutional effects of the sewered populations draining into the river above the four intakes, Table 2 has been prepared, giving these totals for three assumed seasonal and flow conditions, both uncorrected and corrected for the influence of acid wastes above Wheeling.

TABLE 2.—ESTIMATED TOTAL SEWERED POPULATIONS IN 1930 ABOVE FOUR OHIO RIVER INTAKES AND THEIR CALCULATED EQUIVALENTS AT EACH INTAKE, ALLOWING FOR NATURAL PURIFICATION UP STREAM.

(Uncorrected and corrected for effects of acid wastes above Wheeling, W. Va.)

Intake	Sewered population above intake (estimated for 1930)	RESIDUAL POPULATION-EQUIVALENT AT INTAKE					
		Uncorrected for Acid Wastes			Corrected for Acid Wastes		
		Winter	Summer (high stages)	Summer (low stages)	Winter	Summer (high stages)	Summer (low stages)
Wheeling, W. Va.	2 186 500	569 150	391 280	167 080	155 800	3 680	1 465
Portsmouth, Ohio	2 846 500	150 790	34 960	18 630	86 680	31 700	16 480
Cincinnati, Ohio	3 152 400	148 850	36 010	12 040	102 320	33 430	10 700
Louisville, Ky.	3 814 900	178 820	19 200	6 420	145 670	17 640	5 370

As would be expected, the most marked effect of the acid wastes is shown at Wheeling under summer low-stage conditions, although it is also apparent at all four intakes under winter conditions. The enormous decrease in the total sewered population-equivalent at Wheeling resulting from the correction for acid effect indicates the large extent to which the discharge of acid wastes above this point reduces the bacterial pollution of the river originating in sewage discharged at Pittsburgh and other points up stream. Under summer conditions the effect of acidity in the upper river would appear, from the comparative values, to exert relatively little influence on bacterial pollution of the river at Portsmouth and below this point. Under winter conditions, some effect is apparent, although of relatively small magnitude.

In Table 3 the population equivalents given in Table 2 have been converted to their corresponding numbers of *B. coli* in the river, using average volumes of flow obtained from the 1914–1916 survey by the Public Health Service and assuming per capita contributions of *B. coli* as derived by Mr. J. K. Hoskins,[11] from observations made by the Public Health Service at the cities previously enumerated. For comparison with these computed values are given the winter and summer average numbers of *B. coli* observed at each intake during the years 1926–1929, inclusive, when river conditions were more stabilized than during the drought years beginning with 1930. With a few exceptions, the calculated *B. coli* densities in the river are shown to be of about the same order of magnitude as those actually observed although somewhat higher, on the average, than the latter, possibly because the calculation has been based on average flow conditions prevailing before the river was fully canalized.

TABLE 3.—CALCULATED NUMBERS OF *B. coli* IN OHIO RIVER WATER AT FOUR INTAKES, BASED ON POPULATION EQUIVALENTS IN TABLE 2, COMPARED WITH SUMMER AND WINTER AVERAGE NUMBERS OBSERVED DURING THE YEARS 1926–1929.

Intake	CALCULATED *B. coli* INDEX PER 100 CUBIC CENTIMETERS						OBSERVED *B. coli* INDEX AVERAGE, 1926–1929	
	Uncorrected for Acid Wastes			Corrected for Acid Wastes				
	Winter	Summer (high stages)	Summer (low stages)	Winter	Summer (high stages)	Summer (low stages)	Winter (December–March)	Summer (May–November)
Wheeling, W. Va.	49 900	238 000	400 000	13 700	2 240	3 760	2 960	4 470
Portsmouth, Ohio	6 380	10 300	19 400	3 680	9 350	17 200	5 630	5 580
Cincinnati, Ohio	5 710	9 580	10 800	4 220	8 900	9 700	3 130	4 040
Louisville, Ky.	5 260	4 440	3 480	4 290	3 200	3 710	2 180	3 150

Making due allowance for this and other possible sources of error, the quantitative relationships shown in Tables 2 and 3 and Figs. 1 and 2 appear to be fairly representative of those which can be expected under present conditions of flow and distribution of the sewered population along the Ohio River proper and its main tributaries. Among their more striking indications are the following:

(1) Under both summer and winter conditions of temperature and flow, a large proportion of the total bacterial pollution of the river at the various water intakes probably originates in wastes discharged within about 200 river-miles above these intakes.

(2) Pollution originating at more distant points up stream is a considerably larger factor in the condition of the river at these intakes during the winter than in summer, although it appears to be outweighed at all times by pollution from more immediate sources.

(3) Acid wastes in the upper river do not appear to exert much influence on the bacterial condition of the river at Portsmouth or farther down stream, but are a powerful factor within and immediately below the Pittsburgh-Wheeling Zone. In that region, in the absence of sewage treatment, the present acid condition of the river undoubtedly has prevented excessive bacterial pollution of raw-water supplies and a consequent intolerable over-burdening of water purification systems.

From these indications it might be inferred that efforts to reduce over-pollution of the river at various water intakes, or to prevent such over-pollution where it does not now exist, would logically be aimed primarily at sources of wastes discharged within about 200 river-miles above these points and, secondarily, at more important sources, such as the Pittsburgh-Wheeling District, farther up stream. The present benefit received from the presence of acid wastes in the upper river, although it appears to be confined largely to that section of the river and points immediately below it, is of such magnitude that the removal of these wastes, or their substantial reduction, doubtless will bring about a serious over-burdening of water purification plants both in this upper section and possibly at some points below Wheeling, unless provision is made for extensive treatment of sewage, now discharged into the river, both directly and indirectly, at points above Wheeling.

The space limitations of this paper do not permit a similar analysis of survey data on oxygen balance requirements, although it may be pointed out that such an analysis probably would be somewhat more localized in its character and would deal more especially with summer low-water conditions in river stretches extending within and immediately below major zones of pollution. Although a considerable amount of basic data for such an analysis is available from the two surveys made by the Public Health Service in 1914–1916 and 1930–1931, and from more recent local surveys, these data probably need considerable extension along the lines previously indicated.

In conclusion, it may be desirable to add that before any final program of corrective measures in the Ohio River Basin is undertaken, thorough study should be given to the question of adapting degrees and methods of sewage and industrial waste treatment to the various requirements to be met in relieving over-pollution of the river in different zones. These methods, in so far as sewage is concerned, may range from sedimentation and simple chlorination to complete biological oxidation, with chemical treatment possibly falling into an intermediate position. Consideration also needs to be given to the possible effects of various kinds of treated effluents on the river below their points of discharge, particularly in pooled sections under summer conditions. These and a few other similar questions are of general significance and fall more especially in the field of research, which in the long run must keep pace with that of the sanitary survey, as the two are virtually inseparable in meeting engineering problems of stream-pollution control.

LOW-FLOW REGULATION BY PYMATUNING RESERVOIR

BY CHARLES E. RYDER,[12] ESQ.

SYNOPSIS

Pymatuning Reservoir, with a capacity of 8 365 000 000 cu ft, has been built in Northwestern Pennsylvania at a cost of approximately $3 700 000 for the primary purpose of regulating the flow of the Shenango and Beaver Rivers. A part of the project area is used as a Game Refuge, and there are opportunities for hunting, fishing, and other forms of recreation. These uses require careful evaluation of conflicting interests to determine how the project may be operated to serve best the needs of the region. Industries in the valley below require large quantities of water, especially for cooling purposes. The load on water-works filtration plants had been gradually increasing, and the State Department of Health was insisting upon the installation of sewage treatment plants to provide for the removal of settleable solids, oxidation, and chemical disinfection. Since the adoption of the reservoir plans, this high degree of treatment has not been required. Recreation interests demand that the reservoir be maintained at the highest possible elevation. Releases were made during the filling of the reservoir sufficient to satisfy the minimum industrial requirements. Since filling, tests under varying conditions of reservoir releases have been, and will continue to be, made at sampling stations established at a number of locations in the Beaver and Shenango Basins. The tests apparently show that the requirements for sanitation and public water supplies will be the criterion for releases, and a tentative operating schedule was adopted and used in 1937. Provision is made for flood regulation by the installation of flash-boards in the main spillway, and by maintaining the reservoir level below spillway elevation during the winter months. The reservoir was of material assistance in reducing flood heights during the floods of 1936 and 1937.

Pymatuning Reservoir (Fig. 3) is in the Beaver River Basin, at the headwaters of the Shenango River, in Crawford County, Pennsylvania, about 40 miles south of Lake Erie, 90 miles north of Pittsburgh, Pa., and 60 miles east of Cleveland, Ohio. When full, the reservoir covers an area of 26.5 sq miles, of which the greater part is the region formerly known as Pymatuning Swamp. It is 18 miles long, has a shore line of 70 miles, a maximum width of 2.2 miles, and an average width of about 1.5 miles. The maximum depth of water is about 35 ft and the capacity is 8 365 000 000 cu ft at the spillway elevation, 1 008 ft above mean tide at Sandy Hook, N. J.

FIG. 3.—PYMATUNING RESERVOIR AND PARTS OF SHENANGO AND BEAVER RIVER VALLEYS

History of the Project

The completion of the dam in 1934 culminated a long period of interest in Pymatuning Swamp. In 1868 the General Assembly of Pennsylvania ordered a detailed study of the practicability and expense of draining the area and reclaiming land for agricultural purposes. A survey was made and a favorable report submitted, but nothing further was done at that time. In 1907 the Pennsylvania State Highway Department was authorized to make a survey and study for draining the swamp and improving the highways. The resulting plans were submitted to the Water Supply Commission of Pennsylvania for approval, and hearings were held at which objections were raised on the ground that the swamp was a valuable water-storage area which helped to maintain the dry-weather flow of the Shenango and Beaver Rivers. The hearings quickened public interest in a proposal to convert the swamp into an artificial storage reservoir for increasing the dry-weather flow of these rivers, and the Commission finally refused to approve plans for draining the swamp. The Legislature in 1911 passed an Act appropriating $10 000 to the Water Supply Commission, directing it to examine the feasibility of a reservoir project. The Commission reported to the Legislature of 1913 that the construction of a storage reservoir was feasible, and that such a project would result in accrued benefits to the State at large, as well as to the communities along the stream. The estimated cost, including the dam and spillway, highway and railroad changes, purchase of land and buildings, clearing the reservoir site, and improving the shores, was $1 556 402.

Following this report, the Legislature in 1913 passed the "Pymatuning Dam Act," which directed the Water Supply Commission to erect a dam at the outlet of Pymatuning Swamp for the purpose of establishing a reservoir to conserve the water entering the swamp and to regulate the flow in the Shenango and Beaver Rivers. This Act carried an appropriation of $100 000. During subsequent sessions of the Legislature, various laws relating to the project were enacted, most of them carrying appropriations in varying amounts but frequently containing provisions which made it impossible to use the money. The first land purchases were made in 1921, but actual construction work was not started until 1931, when the Legislature appropriated $1 500 000 for the construction of the Pymatuning Dam and Spillway.

There were three major construction items, each let under separate contract; (1) The dam and spillway; (2) an embankment to carry a highway across the middle of the lake; and (3) an embankment to carry the Pennsylvania Railroad and a highway across the lake near its upper end. This latter embankment was built to form a secondary dam, thereby creating an upper lake, 2 500 acres in extent, which is maintained at an approximately constant elevation of 1 010 ft above sea level, or 2 ft higher than the spillway of the main dam. This water area and the adjoining State-owned land have been set aside as a wild life sanctuary 3 670 acres in extent.

An area of more than 20 000 acres of land was purchased in Pennsylvania for the project, and more than 5 000 acres in Ohio—the latter by private interests, principally steel companies of the Shenango Valley. About one-fourth of the lake extends into the State of Ohio.

Cost of Project

The total cost of the project, as completed in 1934, was $3 717 739. In addition to the various State appropriations, $170 000 was advanced from Federal Reconstruction Finance Funds for use as a part of the clearing allotment which was completed with relief labor, and $415 000 was raised by the Pymatuning Land Company for the acquisition of Ohio lands.

Appropriations and donations were expended under the following general sub-divisions:

Surveys for feasibility of project		$ 10 000
Surveys, engineering investigations, and land appraisals		90 859
Land acquisition		1 101 756
Clearing Reservoir Site:		
State appropriations	$618 201	
Federal Reconstruction Finance Funds	170 000	788 201
Construction of dam		368 139
Construction of highway across reservoir		419 547
Relocation of railroad and highway		304 899
Relocation of State Highway Route No. 206		27 060
Reconstruction of Blair Road		1 894
Relocation of telephone lines		3 445
Reforestation of land around lake		5 745
Construction of measuring weirs on Sugar Creek and Shenango River		3 799
Improvements to buildings and grounds		6 538
Administration, supervision, and incidental expenses		170 857
Acquisition of Ohio lands by Pymatuning Land Company		415 000
Total		$3 717 739

Present Status

On December 5, 1933, the gates were closed in the upper dam and on January 23, 1934, the four regulating gates were closed in the main dam. The upper basin, with a storage of 448 000 000 cu ft at Elevation 1 010, was filled and overflowing on March 4, 1934.

The main regulating gates in the lower dam were operated to some extent during the summer months of 1934, 1935, and 1936. During 1937 the reservoir has been operated to regulate floods and to increase low-water flows in accordance with a tentative schedule. The quantities of water released during 1934 and 1935, while the reservoir was filling, were based upon the actual quantities necessary for the operation of the industrial plants at Sharon, Pa., then operating at less than full capacity, and were much below the amounts which will be required to insure the minimum flow necessary in normal times for water supply and for sanitation purposes.

By March 24, 1936, the water reached the spillway level for the first time, and seven days later the lake attained its maximum stage at Elevation 1 008.81, due to rapid run-off from rains and melting snow. On March 28, 1936, the gates were opened to release the flood waters and to provide additional flood-storage capacity. They were closed again from May 13 to May 25, since which date they have been operated continuously until November 2 for the purpose of increasing the flow in the Shenango and Beaver Rivers. In the early part of 1937, the reservoir was operated to control floods, and from June to November to maintain a low-water flow of at least 200 cu ft per sec at Sharon, in accordance with a schedule of operations tentatively adopted.

PURPOSE OF THE PYMATUNING RESERVOIR

The primary purpose of the reservoir, as stated in the original Pymatuning Act of July 25, 1913, and in later amendments, is to conserve the water entering the Pymatuning Swamp, and regulate the flow therefrom so as to maintain, throughout the year, as regular a flow of water as possible in the Shenango and Beaver Rivers. It was further specified that the reservoir, and the land surrounding it acquired by the Commonwealth, might be developed and used for fishing, hunting, game refuge, recreation, park, or other purposes; provided that such uses would not, in the opinion of the Water and Power Resources Board, materially interfere with the primary purpose.

The Water and Power Resources Board was vested with complete and final authority concerning the use and development of the land and water comprised within the project boundaries, and the maintenance and operation of the project. Later, it was provided that the Department of Forests and Waters, with the approval of the Water and Power Resources Board, might enter into agreements with other departments, boards, or commissions of the Commonwealth of Pennsylvania and the State of Ohio relative to the use of the reservoir and surrounding lands for fishing, hunting, game refuges, and other purposes.

It is clear that the mandate of the Legislature with respect to the operation of the reservoir was to store and conserve flood waters during the winter and spring months, and at other times when the natural flow was in excess of the needs in the Shenango and Beaver Valleys, so that such stored waters could be released to make the flow as uniform as possible during the summer and fall months, and at other times of deficient flow from the tributary drainage area. In other words, the Pymatuning Reservoir must be operated so as best to meet the needs of the valley below it for public water supply, sanitation, industrial water supply, navigation, water power, recreation, and esthetic purposes. In addition to such low-water control, it is equally certain that the Act provides for the regulation of the flow from the standpoint of the reduction of floods in the valley below the dam.

The Water and Power Resources Board must accordingly evaluate conflicting interests and determine how the project may be operated to best serve the particular needs of the valley. For example, to secure maximum flood-control benefits, sufficient storage capacity must be preserved in the reservoir to collect flood waters originating above the dam during the winter and spring seasons, and hold them back until the river down stream has receded to below flood stage. On the other hand, such dry storage capacity must necessarily reduce the total quantity of stored water which otherwise might be made available for release during dry seasons. It, therefore, reduces, to a greater or less degree, the efficiency of the reservoir as a regulator of the stream for water supply, sanitation, and other purposes. Fortunately, the water-surface area of the Pymatuning Reservoir is so great at spillway elevation that a storage depth of about 2 ft will afford complete control of the inflow under the worst known flood conditions. Hence, by providing such storage above spillway elevation the reservoir may be depended upon, with only a comparatively small loss in efficiency, to regulate the dry-weather flow.

Another very important phase of the project as a whole must be given consideration, namely, the use of the reservoir for fishing, boating, hunting, and other forms of recreation. For this purpose the lake level should be kept as nearly constant as possible. This requirement naturally is incompatible with releases during the summer season; hence, the reservoir should not be drawn down by releases more than is necessary to afford adequate stream-flow regulation. Although the Legislature was most careful to define the primary use of the Pymatuning Reservoir, nevertheless it must be borne in mind that the principal interest of the project to a large majority of the people in Western Pennsylvania and Eastern Ohio is the recreational value it will afford.

There are then three more or less conflicting purposes to consider in working out a schedule of reservoir operation. Fortunately, it appears from the studies made so far that the requirements for all three purposes can be met satisfactorily.

Need for Low-Water Control

There has long been a need for augmenting the low-water flow of the Shenango and Beaver Rivers. Prior to the completion of the reservoir the Sharon-Farrell District, 35 miles below the dam, with a population of about 45 000, had continuously been subject to shortages of water for domestic and industrial uses during dry seasons. The City of New Castle, Pa., about 20 miles below Sharon, with a population of approximately 50 000, and numerous other smaller intervening localities were likewise affected. The shortage was felt also in the Beaver Valley, where the cities and towns for a distance of 20 miles are rather closely grouped, with an aggregate population exceeding 50 000. The steel and other mills along both rivers require adequate water for economic and efficient operation. Periods of deficiency were a yearly occurrence and always curtailed operations at some of the mills. During dry seasons, water was re-used several times and as a result its temperature reached as high as 140° F. In the summer of 1933, the water was so low at Sharon that even by re-using it, there was not enough for operating purposes. The steel mills were considering closing down, when the small quantity of water that had been stored in the reservoir during construction was released and proved sufficient to tide them over the critical period.

Water-works taking their supplies from the Shenango and Beaver Rivers serve about 175 000 people, with intakes and filtration plants at Sharon, New Castle, West Pittsburgh, Beaver Falls, Pa., and New Brighton, Pa. Prior to the construction of the Pymatuning Reservoir, the Department of Health reported that the load on the water filters was gradually increasing. This condition was recognized as a menace to public water supplies, and was creating a nuisance in the Shenango and Beaver Rivers. At Sharon, flows as low as 8 cu ft per sec were experienced. Flows of less than 30 cu ft per sec were almost a yearly occurrence, and extended over periods of several months at least three times since 1930. The natural flow at New Castle was scarcely 20% greater than that at Sharon during drought seasons.

SEWAGE TREATMENT WORKS

Prior to the passage of the Pymatuning Act the Pennsylvania Department of Health properly insisted upon the installation of sewage treatment works by all municipalities discharging sewage into the Beaver and Shenango Rivers, or any of their tributaries, above the intakes of public water-works. The treatment plants were required to provide for the removal of settleable solids, oxidation, and chemical disinfection. The Department recognized, however, that with the Pymatuning Reservoir in operation, the releases during dry seasons would naturally improve the condition of the river water so that sewage-plant effluent could be safely assimilated with a lesser degree of treatment. Upon the basis of information furnished by the Water and Power Resources Board as to the amount of regulated flow which could be secured through the operation of the reservoir, it was decided that oxidation would not be required. Plans for sewage treatment works in various municipalities in the valley have accordingly been approved and works have been constructed that do not involve the high degree of treatment that otherwise would have been necessary.

LIMIT OF LOW-FLOW REGULATION

The original studies made to determine the maximum amount of regulation which could be secured through the operation of the Pymatuning Reservoir covered the period from 1908 to 1930, just prior to the actual construction of the dam. They did not include the series of dry years beginning in 1930. Within this period the most critical years were found to be 1922 and 1923, and during these years it was found that a minimum flow of 400 cu ft per sec could be maintained in the Shenango River, at Sharon, throughout the year without completely emptying the reservoir. However, to maintain this flow throughout the entire year would have meant a waste of water, as the full quantity was not necessary during the winter months. Accordingly, the calculations were revised to provide a minimum flow of 400 cu ft per sec at Sharon for the months of July, August, and September, 350 cu ft per sec through June and October, and 300 cu ft per sec for the remainder of the year.

Then came the drought years, beginning in 1930, and it was found that the reservoir, if operated on this schedule, would not have been fully replenished in 1930, 1931, or 1932, and that by November, 1933, the storage would have been exhausted.

As a result, a new analysis was made of the dependable yield which could have been secured from the reservoir had it been in operation for the critical period from 1929 to 1935. This investigation was based upon releases to maintain a minimum flow at Sharon of 200 cu ft per sec during the months of June, July, August, and September; 150 cu ft per sec during May and October; and 100 cu ft per sec during the remaining months of the year. With these releases the reservoir would have filled each year, and the maximum draw-down would have amounted to 3.9 ft. Corresponding computations covering the years 1908 to 1929 have not yet been made, but it seems probable that in normal years the fluctuation in the reservoir would hardly exceed 2 ft.

It is scarcely necessary to explain that the assumptions of minimum rates of flow to be maintained at Sharon are not to be construed as the actual flows which would have occurred throughout the period. The actual flow, particularly during the winter and spring months, would have greatly exceeded the minimum figures indicated, due to the higher rates of run-off from the tributary drainage area below the dam, and to overflow from the reservoir itself.

TESTS TO DETERMINE WATER REQUIREMENTS

When the reservoir filled for the first time, in the spring of 1936, it became possible to release varying quantities of water and to study the resulting river conditions. Establishment of a definite program of reservoir operation has been delayed pending the completion of these tests, which are being conducted by the Engineering Bureau of the Pennsylvania State Department of Health. However, a tentative program was adopted in July, 1937.

Sampling stations were established at various locations in the Beaver and Shenango River Basins, as shown in Fig. 3. Then a series of test runs was made, with water released from the Pymatuning Dam to maintain as closely as possible a given specified flow at Sharon. The first four runs were as follow:

Dates of analytical traverses	Flow, at Sharon, in cubic feet per second	Release from dam, in cubic feet per second
June 3, 1936	111	88
June 15, 1936	215	140
July 17, 1936	240	200
August 27, 1936	490	93

The tests of the water made by the Department of Health included:

Alkalinity and pH: To determine the reaction of the stream before and after receiving industrial wastes, particularly pickling acid.

Dissolved Oxygen: To determine oxygen available to prevent nuisance by assimilating decomposing organic matter; also to determine whether stream was capable of supporting fish life.

Bio-Chemical Oxygen Demand: To determine the amount of decomposable organic matter present, and, by comparison with the results of the dissolved oxygen test, to determine whether the pollution load is greater or less than can be assimilated by the dissolved oxygen and still leave a safe oxygen balance.

Color: To determine effects of colored swamp water from Pymatuning Reservoir upon water-works.

Iron: To determine effect, other than oxygen depletion, of metallurgical industrial wastes.

The information given in Table 4, was furnished by the Department of Health with respect to sewage load and present methods of treatment in the larger towns in the Shenango and Beaver Valleys.

The studies indicated that the stream discharges tested were not large enough to provide sufficient oxygen in the diluting water to put the river in satisfactory sanitary condition below the sewage and industrial waste discharge from the Sharon-Farrell District and, at times, below New Castle and, again, at the mouth of the Beaver River; and in 1937, acting upon the advice of the Department of Health, a tentative schedule of reservoir operation was adopted to provide for a minimum flow at Sharon of at least 200 cu ft per sec, during June, July, August, and September; 150 cu ft per sec, during May and October; and 100 cu ft per sec, during the other months of the year. Further studies are to be made by the Department of Health.

TABLE 4.—PRINCIPAL SEWAGE LOADS IN SHENANGO AND BEAVER VALLEYS

Town or district	Population	Nature of effluent	Remarks
Sharon, Pa.	21 000	Treated	Removal of settleable solids
Sharon, Pa.	5 000	Raw	....
Farrell, Pa.	14 000	Raw	Primary sewage treatment works now under construction
In Ohio Near:			
Farrell-Sharon-Farrell, Pa.	3 000	Raw	....
Sharpsville, Pa.	5 000	Treated	Removal of settleable solids
Total equivalent population, raw sewage load	39 000	....	....
New Castle, Pa.	45 000	Treated	Removal of settleable solids
West Pittsburgh, Pa.	1 000	Treated	Removal of settleable solids
Elwood City, Pa.	12 000	Treated	Removal of settleable solids
Koppel, Pa.	1 000	Treated	Removal of settleable solids
Beaver Falls, Pa., and vicinity	30 000	Treated	Removal of settleable solids

At present it appears that the criterion for releases from the Pymatuning Reservoir will be the requirements of sanitation and public water supplies, and that if such needs are met, or met approximately, there will be more than sufficient water for industrial purposes. It also seems that the Sharon-Farrell District is the critical one with respect to sewage load and industrial wastes. The Department of Health is now taking steps to reduce materially both sewage and industrial pollution originating in this district.

The State has done its part in building the Pymatuning Reservoir to increase normal low flows in the Shenango River sufficiently to assimilate reasonably treated sewage and industrial wastes. The municipalities and industries should likewise be expected to co-operate in bringing about a reasonably clean stream, which will add materially to the attractiveness and economic advantage of the entire valley. It certainly should not be permissible for a small group of municipalities or industrial plants to continue to place a heavy pollution load upon the stream when, by taking reasonable measures to eliminate or reduce such loads, it would be possible to curtail greatly the releases and thus lessen the yearly fluctuation in the reservoir. There would seem to be too much interest by the public at large in the recreational use of the area for the State to countenance such gross and unwarranted pollution.

Indications point to a need, for sanitary purposes, of at least 200 cu ft per sec at Sharon and possibly more during the hot summer months. The requirements during the colder months will be much less, probably less than one-half the summer maximum. Industrial requirements for water for the Sharon District appear to be greater than for the New Castle and the Beaver Valley Districts, and these requirements during the most critical months of 1936 (June, July, and August) did not exceed 150 cu ft per sec and were closer to 100 cu ft per sec the greater part of the time. This is significant when it is recognized that those mills requiring by far the largest quantity of water were operating generally at 90% to 95% capacity during July and August.

Flood Control

Although this paper is limited primarily to the effect of the Pymatuning Reservoir in regulating stream flow for dilution purposes, it would not be complete without some reference to the flood-control aspects of the project, as the operation of the reservoir for one purpose affects its usefulness for others.

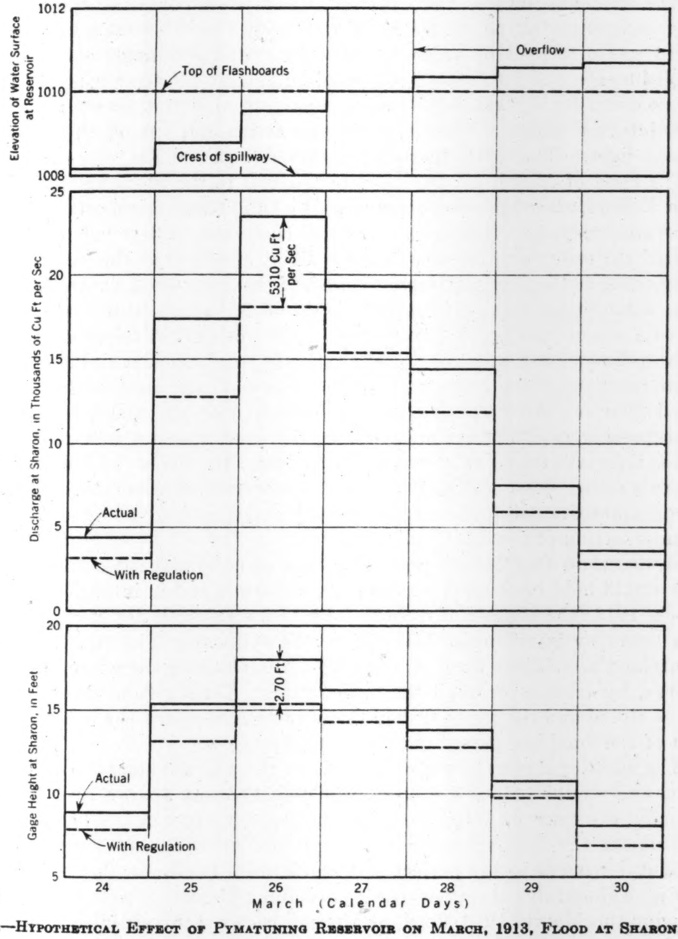

Fig. 4.—Hypothetical Effect of Pymatuning Reservoir on March, 1913, Flood at Sharon, Pa.

Thirteen disastrous floods have been experienced in the Beaver River Basin since 1806, the year of the first major flood of record. Little authentic information is available concerning them prior to 1884, although there is evidence that the flood of 1832 may have exceeded the two major floods of 1884 and 1913. This flood occurred before the valleys were densely populated and when few obstructions existed in and along the river channel.

The largest and costliest flood of recent years was that of March, 1913. Its magnitude and effect are comparable to that of the 1936 flood in other sections of Pennsylvania, and every city and town bordering the river was either completely or partly submerged. Bridges were swept away, railroad service was disrupted by numerous washouts, and dwellings, manufacturing establishments, and business places were inundated. Water-works were forced to shut down for several days, and on resuming operation pumped unfiltered water into the mains. Water entered gas mains and cut off the supply for fuel and light. The total reported loss exceeded $2 000 000.

The flood of March 17, 1936, did not extend to the Shenango and Beaver River Valleys, although other streams in the Ohio River Basin established new high-water records. Reports emanating from the valley below the dam credited the reservoir with preventing a disastrous flood at this time, but this was not true as the precipitation over most of the water-shed was in the form of snow, rather than rain. However, on March 25, a moderate flood occurred due to a warm rain and melting snow. The reservoir level was then 0.7 ft below spillway crest, and the storage capacity was sufficient to hold back the waters from the drainage area above the dam until the crest of the flood had passed Sharon. After the flood had subsided there was a small quantity of water passing over the spillway which, however, did not add to the flood height; later, the lake was drawn down gradually to provide additional storage in case another flood should follow. The reservoir reduced the discharge at Sharon approximately 25% and prevented overflow and flood damage in the business section of the city.

Studies show that 2 ft of storage above the spillway elevation of Pymatuning Dam would hold back flood waters from a storm equal in intensity to that of March, 1913 (the highest of record). Provision for such dry storage has now been made by installing a 2-ft weir in the spillway. The reservoir will be maintained at spillway level, or somewhat lower during the winter and spring months, by releases through the outlet gates. During flood flows the gates will be closed and the reservoir will then function to retard the inflow until the crest of the flood has passed out of the valley below.

The additional storage made available by the weir amounts to 1 297 000 000 cu ft, and would reduce the crest of a high flood at Sharon by 2.5 to 3 ft. Actually, the reservoir might be maintained about a foot or two below spillway crest during the flood season, and thus provide an additional factor of safety, without detriment to the project as a regulator of low-water flow.

Fig. 4 illustrates the effect the Pymatuning Reservoir would have had in reducing the March, 1913, flood, at Sharon, with a 2-ft weir in the spillway of the dam.

Benefits of Reservoir in 1936

During 1936, the first year of experimental operation, benefits derived from the reservoir at least met expectations as to the value and usefulness of the project. Tests of both its flood-control and low-flow replenishment features came quickly.

During the summer of 1936, the Beaver River and, especially the Shenango River Basin, experienced a very dry season. Although the drought was not so severe as that of 1930, nevertheless, it threatened to approach that condition and was, in effect, comparable to those of 1932 and 1934. Starting with a full reservoir, the gates were operated continuously from May 25 to November 2 to meet demands, primarily, in the Shenango Valley. During this period the average release was 100 cu ft per sec, and at no time was it less than 50 cu ft per sec. The average resultant flow maintained at Sharon was 175 cu ft per sec, and the lowest daily flow was about 100 cu ft per sec. Had there been no storage to help, the flow at Sharon could not have exceeded 30 to 40 cu ft per sec during the greater part of the time and would probably have been less over short periods.

Flood-control operations of March, 1936, have already been mentioned. Although the March run-off in that year failed to approach a record high stage, it was high enough to produce a secondary flood along many stretches of the Shenango River. Without the reduction in stage effected by the Pymatuning Reservoir, the damage in this valley would have been considerably greater than actually occurred.

At the end of 1936, consensus of opinion in the districts benefited could have been summed up in the expression, "We feel that the dam has already paid for itself."

Until the Engineering Bureau of the State Department of Health completes its investigations and submits its final report to the Water and Power Resources Board, no definite plan will be established for rates and periods of release from the Pymatuning Reservoir. Even after a plan of operation is adopted, it will probably be necessary to modify it as actual experience is gained from year to year, and as conditions change in the valley below with respect to public and industrial water supply, sanitation, etc. It is certainly to be expected that, under efficient regulation by the Sanitary Water Board, the pollution load will become no greater than it is at present, despite probable increases in population and industry.

SANITATION PROBLEMS INCIDENTAL TO FLOODS

BY W. L. STEVENSON,[13] M. AM. SOC. C. E.

SYNOPSIS

In time of flood, public health authorities and municipal and water-works officials are confronted with a variety of emergency sanitation problems that demand immediate attention. It is important to be prepared in advance. This paper outlines the major factors in such planning, and makes suggestions for the conduct of activities during floods and as the waters recede. Experience in Pennsylvania in 1936 is drawn upon for many of the details.

Although flood-control reservoirs can reduce maximum flood stages, and dikes can safeguard more or less limited areas against inundation, it requires large sums of money and long periods of time to develop such projects. In fact, it is inconceivable that all rivers can ever be controlled so that flood stages will not occur at times. Therefore, preparation to meet the sanitation problems incidental to flood disasters must still be made.

For the purpose of this paper, the word, sanitation, simply means the keeping clean of the environment of Man or making it clean; and, in this sense, cleanliness means the absence of dirt resulting from Man's life and work.

Rivers draining developed areas must receive and carry away sewage, industrial wastes, and the rain-water run-off from towns and cultivated fields. Where sewage and some industrial wastes are inadequately treated, and the receiving stream at normal or low stages is too sluggish to be self-cleansing, then sludge deposits form on the bed of the river. Consequently, flood waters are always dirty, and more or less befoul inundated communities and water-works, thus creating a serious emergency sanitation problem.

The principles of sanitation are well known and in daily use. What creates the acute problem in sanitation incidental to floods and makes difficult the application of these principles, is the need for immediate action and the difficulties of transportation and communication. Seemingly everything must be done at once and everywhere at the same time, but floods prevent normal transportation and communication. Men and materials immediately needed in the stricken areas have to be taken over long detours because of inundated highways and railroads and washed-out bridges. The enormous load of business upon telephone and telegraph wires caused by flood conditions swamps their reduced capacity and makes it difficult even to ascertain the sanitary needs of the flooded areas.

The fact that floods inevitably produce these conditions makes apparent the importance of preparing and planning for preventive and corrective sanitary measures before the next floods actually arrive. This paper considers the problem in three steps: (1) Present planning and work; (2) things to be done during floods; and (3) things to be done as the waters recede. The suggested course of action is predicated upon the doctrine of home rule; that is, the primary responsibility should rest upon local authorities, with State agencies guiding and correlating activities and helping as far as possible, especially in the rural areas and smaller municipalities.

---

[13] Director, Bureau of Eng., Pennsylvania Dept. of Health, Harrisburg, Pa.

PRESENT PLANNING AND WORK

Water-Works.—In recent years, the trend in public water supply projects has been toward the development of impounded, relatively clean, upland sources delivered by gravity, in preference to the use of polluted river water that requires a high degree of purification, and that must be pumped as well. Those in charge of water-works subject to danger from floods should study the practicability and advisability of obtaining upland water, so as to eliminate the flood menace to low-lying water-works, and simultaneously secure a superior water supply. Even with an upland source, however, care should be exercised to safeguard all the mains at places where they may be endangered by floods; otherwise, the areas served by such mains will be no better off than if they were served by a low-level source of supply.

In Pennsylvania, during the floods of 1936, most of the communities with upland gravity supplies not only had water during the flood, but also had enough water in storage for clean-up purposes afterward. The opposite condition occurred at many of the low-level water-works, which were flooded.

Adequate storage capacity for purified water is always needed to meet drought conditions. For this purpose the storage facilities of many water-works have been enlarged since the droughts of 1930 and following years. Nevertheless, during the March, 1936, floods in Pennsylvania, many storage reservoirs were exhausted before the emergency was over, despite the fact that they were well filled before the flood, and that restrictions were enforced to prevent waste while the water-works were shut down.

Officials of such water-works should now give attention to their storage facilities, and if they find them to be inadequate, they should take the needful steps to enlarge them as a safeguard against future drought or flood.

Of the 106 water-works adversely affected by the floods of 1936 in Pennsylvania, the following parts were put out of operation: Pumps in 61 plants; chlorination apparatus in 35; clear wells in 23; filters in 13; and chemical feed apparatus in 13. Inundated motors had to be baked, which caused delay in resuming operation. Flooded switch-boards took time to clean. The flooding of filters or clear wells was most dangerous.

Water-works officials should study their plants to determine whether the vital parts can be raised above maximum flood height. If raising, in whole or in part, is found to be impracticable, then consideration may well be given to providing substantial flood guards for doors and windows of low-lying pumping stations, which could be put in place when floods occur. The building of dikes might also be considered. However, if the top of a dike is not surely above maximum flood height, then after the flood the dike will retain the flood waters and cause further delay in getting the water-works back into service. A sluice-gate set at a low elevation in such a dike would be a help in draining impounded water.

Other matters to be considered are auxiliary sources of power, duplicate and well-protected water mains under rivers (with proper valves at each end to prevent loss of water in case of pipe failure), adequately valving the distribution system to provide flexibility of operation, and emergency connection with the mains of a near-by water system.

The doctrine of home rule applies to water-works. It is the duty of water purveyors to have competent works operators, capable on short notice to take charge of emergency work, and to handle their plants successfully when disaster threatens.

Municipalities.—In some municipalities with public water supplies the residents of areas subject to flooding still obtain their drinking water from private wells. In such cases, consideration should be given to extending the public water mains into the low-lying parts of the town site. Flooded private wells are a grave menace to health, and the best way to eliminate the hazard is to replace them with a safe, piped, public water supply. Meanwhile, the local board of health should prepare a map showing the location of all private wells in areas subject to flooding, so as to be prepared, when floods come, to direct their cleansing and sterilizing without delay.

No privies or cesspools should be permitted on properties to which a public sewer is accessible, for they are an actual or potential health menace at all times, and especially when flood waters carry the night soil into water wells and into houses.

In Pennsylvania, the clean-up of flooded dwellings in 1936 was markedly expedited by help from Federal Work Relief agencies, such as the Works Progress Administration and the Civilian Conservation Corps. It may be that when severe floods next occur, these valuable aids may not be available. Therefore, municipal officials would do well to make general plans for flood clean-up work and file them away, so as to be prepared to handle the job with their own facilities and labor. Then when the emergency comes they will be ready to proceed with a minimum of State supervision or aid. In cities such plans might include the establishment of refugee centers, first-aid stations, and emergency hospital facilities. It is not to be expected that the small municipalities can handle such a problem without help.

The State.—There are some services which the State Government can and should render in flood disasters. First, it should supply forecasts of the flood stage and time of cresting, in order that local authorities may be duly forewarned. Further, the National Guard can augment local police and completely take over police duties in the rural districts to prevent looting. The State Health Department can correlate measures for the prevention of disease and take charge of public health work in the rural districts and weaker municipalities.

Considerable planning should now be done along these lines, in order to be generally prepared for future floods. This preparatory work may include urging municipal and water-works officials to make suitable and practicable plans for meeting flood disasters in their own communities.

Hydrography.—After the March, 1936, floods in Pennsylvania, U. S. Army Engineers and the Pennsylvania Department of Forests and Waters in cooperation with the U. S. Geological Survey collected as much information as possible along certain main rivers as to the maximum height reached by flood waters and the day and hour of cresting. Levels were then run to ascertain the elevation of these marks. From these data maximum flood profiles were plotted and the time of transit of the crest height from place to place was determined.

Such information is so valuable in planning for the future that where it has not been undertaken as thoroughly as in Pennsylvania it should be begun at once. (Plans should also be in readiness, in case of future high floods, for establishing high-water marks on stable structures as soon as possible after the crest has passed.) In connection with this work it would be helpful to locate the horizontal limits which the flood waters have reached in built-up communities. With such data available, municipal and water-works engineers can make plans intelligently for changing existing structures or designing new ones, as far as floods are concerned.

The maintenance of stream gaging stations at strategic points is important. At stations that are difficult of access at flood stage, auxiliary gages should be established well back from the normal channel of the river in order to assure positively continuance of the record during the period when it is most needed for flood forecasting.

The value of accurate flood forecasting to health authorities, to water-works operators, and to the public at large, is so great as to warrant the development of a nation-wide service organized to the maximum possible degree of efficiency and dependability.

When the flood emergency comes, it is vitally essential that gage-height readings be reported promptly to the central authority. This indicates the wisdom of the special arrangements that have already been made with telephone companies in some States, to maintain telephone service as long as possible during floods between the gage readers and the central office of the hydrographers. Consideration is also being given to the use of radio for this purpose.

Health Departments.—State Health Departments should prepare for future floods by making plans for establishing, equipping, and manning first-aid stations in flooded districts, and for the distribution of needed biological products. Mobile bacteriological laboratories have proved to be valuable in the ordinary conduct of the business of State Health Departments, and they are especially valuable in flood-emergency work. Therefore, it would be well for State Health Departments not now provided with such facilities to endeavor to obtain them.

The number and location of Highway Department and National Guard mobile water tanks naturally change from year to year. It is futile, therefore, to prepare an inventory of such equipment and make definite plans, long in advance, for their use in hauling drinking water to stricken communities during a severe flood. However, where arrangements do not already exist between State Health Departments and such other branches of State Government for the emergency use of such equipment, it appears wise to make such arrangements in a general way, chiefly for the purpose of having immediate co-operation when the emergency comes.

Health Departments should also arrange with telephone companies for the maintenance, as long as possible during floods, of telephone service between the central office of the Department and the headquarters of important field agents, such as district engineers, medical officers, etc.

Things to Be Done During Floods

When it appears that floods are likely soon to occur, the State Health Department should notify all local Boards of Health as to their emergency duties, and give them advice on such matters as cleansing flooded water wells, privies, cesspools, and inundated dwellings and their surroundings. Particular emphasis should be laid on sanitation of milk stations, and warning the public to boil all water to be used for drinking purposes. Similar instructions should be issued to field medical officers of the Health Department as to their duties in rural districts where there are no local Boards of Health.

The Health Department Engineers should warn officials of water-works to store in reservoirs as much purified water as possible and take emergency measures to prevent, as far as possible, submergence of low-lying pumping stations and filter plants; also, where practicable, to make arrangements for temporary connections with the mains of near-by water systems less likely to be affected by the coming flood.

Industrial concerns are often large consumers of the public water supply, and if conditions justify, service to them should be temporarily discontinued. Householders should also be requested to save water, but hospitals and hospital laundries should not be restricted, as water is essential for care of the sick.

As soon as the State Hydrographers receive reports of rising river stages, the data should promptly be transmitted to the main office of the Bureau of Engineering of the State Health Department, whence it should be relayed to the Department's engineers in the field: First, for their information as to which rivers are rising toward flood stage; and second, in order that they may notify the low-lying water-works and communities of the coming danger. At the same time these field engineers should gather as much information as possible on river stages, from water-works or other sources, and report it back to the central office for prompt transmission to the hydrographers to augment their available data. As river stages approach flood magnitude the State Hydrographers should furnish to the Health Department Engineers their forecasts of flood-crest height and the time of cresting at various places. This procedure was used in Pennsylvania during the March, 1936, floods and proved to be of great value to the Health Department in preventing epidemics of disease.

When floods are imminent, but always before inundation occurs, every possible effort should be made by the State Health Department, by local Boards of Health, and by municipal and water-works officials to warn the public to boil all water to be used for drinking purposes. This can be done by means of newspapers, radio, printed notices posted in conspicuous places, and projected on the screen in motion-picture houses, and in all other ways that will receive the attention of the public. In foreign-language communities the warning should be given in the language understood by the citizens.

In recommending a universal warning to boil all water to be used for drinking, it is recognized that a seeming injustice is done to those public water supplies that are able to continue to furnish an entirely safe water during the flood. However, to qualify the "boil water" warnings by specifically including certain public supplies feared or known to be unsafe, and excluding other public supplies believed to be safe, would bewilder the public and lead to confusion thrice confounded. The universal warning was used in Pennsylvania in 1936 and is believed to have played a considerable part in the prevention of disease. There were no epidemics reported from the flooded area.

As soon as it can be determined which water-works are likely to be adversely affected by the coming flood, an inventory should quickly be made of available motorized water tanks for use in hauling pure drinking water to communities whose public water supply fails. These tanks can usually be obtained from State and municipal highway departments, the National Guard, and possibly from milk companies, and gasoline companies.

Where water must be hauled long distances, railroad tank cars may be used, but probably the actual distribution of such drinking water in the stricken town would have to be made by motorized or horse-drawn tank wagons. Every tank to be so used should be thoroughly cleansed and then disinfected with a chlorine solution or by steam under pressure. As a safeguard, it is wise to add a proper amount of a solution of chloride of lime to the drinking water in these tanks at the time they are filled, in order that the germicide may have adequate time to act before the water is served to the public.

Before the floods actually come, officials of municipalities and water-works should make arrangements with vendors of lime and chlorinated lime, so that when the emergency arises telegraphic orders may be placed for the immediate delivery of these disinfectants. The State Health Department should do likewise in order to insure quick delivery of such supplies to flooded rural districts and small municipalities.

Where properly trained persons are available, high-test chlorinated compounds may be used to advantage because of their more definitely known strength, lesser bulk, and better keeping qualities. However, if the chlorine compounds are to be handled by untrained persons (who are likely to use far more than is necessary), then the ordinary bleaching powder is preferable.

As the floods develop, and as soon as a reasonable forecast can be made as to the areas likely to be affected, the State Health Departments should station their mobile laboratories at strategic locations for the prompt bacteriological examination of public and private water supplies.

THINGS TO BE DONE AS THE WATERS RECEDE

After a flood there are hundreds of things to be done, and all of them should be begun simultaneously. More men, materials, trucks, and tools are needed than can be furnished simultaneously throughout the flooded area. Then comes the test of previous careful planning to meet the emergency.

Officials of municipalities, water-works, and the State should, therefore, begin to plan for the clean-up just as soon as it can be forecast what places are likely to be inundated. Then rehabilitation can begin as soon as the flood crest is past. The major sanitary problems at that time are chiefly related to rehabilitating public water-works, cleansing milk stations and private wells, and cleaning up town sites.

Measures to Be Taken by Public Water-Works Officials.—The cleansing and rehabilitation of public water-works is the most important sanitary measure, for widespread disease will surely follow the drinking of a contaminated public water supply. It is not necessary to describe here the innumerable things that must be done to put flooded pumping stations back in service. In particular, however, it may be noted that filters and clear wells must not only be cleansed but sterilized—generally by means of a solution containing free chlorine. Chemical feed and chlorine apparatus which have been under water will need careful attention if they are to function properly when the remainder of the plant is ready for operation. When all these things have been done and the filter plant has been started, the water should be extra heavily chlorinated, and wasted for a while through fire plugs or blow-offs, to insure a good chlorine residual when it is again sent through the distributing system to the consumers. Meanwhile, field crews should be at work repairing broken mains, fire plugs, and house connections.

Speed in the resumption of service must not take priority over safety of the quality of water delivered to consumers. The warning to boil all drinking water should be continued after the flood until a sufficient number of samples of the water throughout the system, upon analysis, show the quality to be perfectly safe.

Cleansing Private Water Wells.—All mud, muck, and débris should be removed from the top of the well and its surroundings. It should then be pumped to waste and a strong chlorine solution applied and allowed to stand not less than 24 hours and preferably 48 hours. Where practicable, and especially where the well cover is not tight, the inside walls of the well should be scrubbed with a chlorine solution. After these things have been done, the well should again be pumped to waste until the ortho-tolidin test shows that chlorine is no longer present. A sample should then be taken for bacteriological analysis.

In this work mobile bacteriological laboratories are of great value. Following the 1936 floods in Pennsylvania, 10 000 samples of public and private water supplies were analyzed in the three mobile laboratories of the State Health Department and 2 000 in the Philadelphia Laboratory. This is about the same number as are normally analyzed during an entire year in the Department's Laboratory.

In cleansing private water wells it will be found that many of them were actually unsafe prior to the flood. After the flood is the psychological time to secure improvements in those found to be faulty in construction.

Milk Supplies.—No raw milk affected by the flood should be served raw. If a pasteurizing plant is flooded, the milk normally delivered to it should be diverted to some near-by unaffected plant the capacity of which can be increased by operating longer hours than usual. Often the employees of the flooded plant can work temporarily in the other one.

Flooded milk stations and pasteurizing plants must be thoroughly cleansed and all milk equipment, bottles, etc., sterilized. The plants should not be put back in operation until all the equipment is in good mechanical working order and all sanitary features have been checked by health authorities having jurisdiction over milk supplies.

The distribution of milk from feeding stations in the flood zone should be restricted to bottled milk.

Cleaning Up Towns.—Men, trucks, shovels, lime, chlorinated lime, and an orderly plan of procedure are needed to remove and dispose of the silt, mud, and débris left by the flood waters in inundated communities. Fortunate is the town whose water-supply reservoirs are full at this time so that an abundance of water under pressure is available for flushing.

Cellars must be pumped out, rubbish removed, and quick-lime applied. The devastation and filth in the rooms of flooded houses are appalling. Here cleansing had best be followed by the use of a solution of chlorine made from concentrated compounds or ordinary chlorinated lime.

In unsewered communities the flood waters will have destroyed privies and washed their night soil on to the surrounding ground. All exposed night soil should be sprinkled with quick-lime or chlorinated lime, according to local circumstances, and buried as soon as practicable at a location which will not menace any water supply. The prompt providing of temporary Army-type latrines is essential to prevent promiscuous defecation until permanent sanitary privies are rebuilt.

Suitable sites must be selected for dumps for the filth and débris hauled away from the flooded town. There is a strong temptation to dispose of such materials in the easiest way by dumping them into the nearest stream that may still be at high stage. If possible, this should not be done, as it only tends to befoul some place down stream, or leave the river banks dirty and littered when the stream returns to normal stages.

CONCLUSION

Flood emergencies try Men's souls and exhaust their bodies. Speed, sympathy, and service are essential. Above all else is needed co-operation and *esprit de corps.* The stricken people in the flooded areas must have confidence in those who are laboring to help and protect them. Of what avail is it for health authorities to warn that drinking water should be boiled and contaminated foods should not be eaten, if the public does not co-operate by heeding the warning?

With skill, zeal, and hard work on the part of those in authority, and co-operation on the part of the public, sanitation work in flood emergencies has prevented and again can prevent epidemics of disease which otherwise are sure to occur. Before the next flood strikes is the time to prepare to meet the sanitation problems it will produce.

PROGRESS IN POLLUTION CONTROL IN THE OHIO RIVER BASIN

By E. S. Tisdale,[14] Esq.

Synopsis

Progress in the control of stream pollution in the Ohio River Basin is summarized from four angles: (1) Plans for sewage treatment; (2) handling of detrimental industrial wastes; (3) development of public opinion favoring water conservation; and (4) Federal laws and compacts.

Under Angle (1), a warning is sounded that something must be done, for in critical drought periods the sewage pollution is becoming too great a burden for even modern water purification plants to cope with. Records show that $12 000 000 have been expended under Public Works Administration and Works Progress Administration programs to improve sewage disposal along the main stem of the Ohio River.

It is pointed out under Angle (2) that co-operative programs between the United States Public Health Service and the States have overcome detrimental phenol pollution and are now reducing acid mine drainage from abandoned bituminous coal mines by air-sealing. The total daily acid mine drainage is estimated to be approximately 15 000 000 lb.

Under Angles (3) and (4) the gradually awakening public opinion is touched upon. The program started as regional water planning in the Cincinnati area. Compact agreements were proposed, and the consent of Congress was obtained for States to work together to reduce stream pollution.

The development of public opinion led to the formulation of definite legislation of a national character, upon which hearings were held. This legislation did not pass in 1936, but is being actively considered by the Congress in 1937.

To obtain a tangible concept of the canalized Ohio River, one may imagine a series of steps or boxes filled with water (Fig. 5). The difference in elevation between the top step, or box, located at Pittsburgh, Pa., and the lowest one, at Cairo, Ill., is 413 ft. In length, this series of fifty-three boxes, with a Federally operated dam in the lower end of each, extends more than 900 miles. Into this canalized river the tributary streams, large and small, empty their waters. The entire drainage area is 200 000 sq miles. It embraces parts of eleven States, having a combined population of about 17 000 000. Great industrialized cities have developed along the river and its tributaries. At the head-waters lie the richest bituminous coal fields in the world and from them comes an enormous pollution load of acid mine drainage.

---

[14] Director, Div. of San. Eng., West Virginia State Dept. of Health, Charleston, W. Va.

The progress in pollution control in the Ohio River Basin may be gaged by the answers to four questions:

(1) What progress is being made in the reduction of pollution caused by human sewage from cities?

(2) What progress has been achieved in the control of industrial wastes?

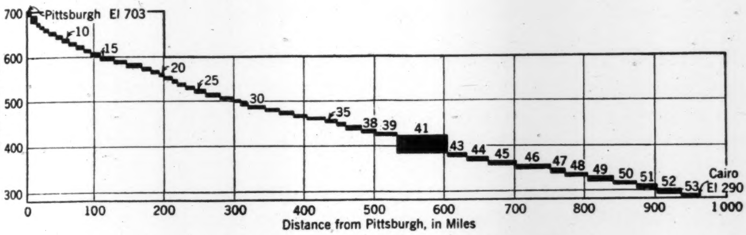

FIG. 5.—SLACK-WATER IMPROVEMENT OF THE OHIO RIVER

(3) What progress can be shown in the development of a "water-shed consciousness," involving co-operation of Federal, State, and local agencies, in conserving the waters of the basin for their varied and most useful purposes?

(4) What progress has been made which will permit co-operative effort of States and local governments in line with comprehensive Federal and interstate plans of pollution control?

PROGRESS IN SEWAGE POLLUTION CONTROL

The first of these "What Progress" questions deals with sewage pollution. It is the most important of them all, because more than 5 000 000 people obtain their drinking water from the water resources of the Ohio River Basin and nearly 2 000 000 from the Ohio River itself. The practice of the past has been for the cities on the Ohio River and its tributaries to conduct their sewage wastes directly to the stream without purification, and it is still the prevailing method in 1936. The cities have considered it their right to utilize the dilution of the large stream as a satisfactory method of disposal.

Although pollution from this source has been increasing, the science of water purification has gone forward, and thus far sanitary engineering has triumphed. Due to the design, construction, and skilled operation of water filtration systems, the public has been protected against water-borne diseases, notwithstanding the pollution of the river. Nevertheless, that there are limits beyond which streams cannot assimilate organic wastes, particularly human sewage, was amply demonstrated during the critical drought periods of 1930–1931, when it became impossible to produce a satisfactory drinking water supply from the putrefying waters contained in some of the basins between Pittsburgh and Cairo.

In January, 1936, the National Resources Committee, interested in developing a comprehensive policy to reduce pollution of the Ohio Basin, requested the Ohio River Board of Engineers (a co-operating group of State Health Department engineers who had been working on pollution control since 1926) to prepare a statement showing the number of persons using the main stem of the Ohio River as a source of drinking water supply, the status of sewerage and sewage disposal in the municipalities along the Ohio River, and a plan for the future betterment of present pollution. The engineers' report showed that the Ohio River itself was the source of water supply for public water-works serving 1 690 000 consumers, and this did not include Pittsburgh. An encouraging note in the sewerage summary in the report was the fact that, since 1932, in five States (Pennsylvania, Ohio, West Virginia, Indiana, and Kentucky) there had been approximately $12 000 000 expended toward construction, with Federal aid, of sewage collection and sewage disposal improvements. An estimate showed that approximately $50 000 000 more would be necessary to provide primary treatment for sewage from all municipalities on the main stem of the river.

There is certainly an element of progress visible in this $12 000 000 expenditure. Since Federal financial assistance has been available for building sewers on the loan-and-grant plan, 20% of the work necessary to afford primary treatment to sewage discharged to the main Ohio River has been finished. The policy of the Health Department in at least one of the States along the river is to give no more permits for extensions to city sewerage systems until the city in question agrees to develop a comprehensive plan for sewage collection and treatment. This is a step in the right direction and if all the States on the water-shed adopt such a policy, the program of reducing sewage pollution will be speeded up.

Among the general remedial measures on sewage pollution control set out in the Board of Engineers' report of January, 1936, was this statement:

> "Every sewered municipality of reasonable size should have a comprehensive plan of sewerage approved by the state health department and should diligently proceed within the limitations of financial ability to construct the intercepting sewers. The larger communities and those situate within harmful influence of waterworks intakes should be the first to install treatment works to effect at least efficient removal of settleable matter. Thereafter, but as soon as practicable, the smaller municipalities should do likewise."

The State health authorities in States along the Ohio River feel that it is becoming increasingly difficult to produce safe, palatable water under critical conditions even with a water purification plant of modern design and skilled operation. Critical periods have occurred in 1930, 1931, 1934, and 1936. Cases of intestinal disorders were noted in the basin in the fall and winter of 1930–1931, even though an acceptable bacteriological standard for water quality was attained. This experience should be a warning that the pollution load from sewage must be reduced, and that a remedial program similar to that carried out since 1932, through the assistance of Federal funds, should be accelerated.

Progress in Industrial Wastes Control

"What progress" with respect to improved practice in industrial wastes disposal is the question which immediately follows, for it is inextricably tied in with sewage disposal. Industries located in cities commonly discharge their wastes into the city sewers. Industrial wastes as well as drainage produced by the development of mineral resources, such as bituminous coal, must of necessity be discharged into the neighboring streams.

Constructive progress in dealing with the disposal of industrial wastes in the Ohio River Basin began about 1924, when the State Health Departments of Pennsylvania, Ohio, and West Virginia met in Pittsburgh under the leadership of the late Director of Health of Ohio, Dr. John E. Monger, and agreed to work co-operatively in handling industrial waste problems where they affected public water supplies. Under the Ohio River Interstate Stream Conservation Agreement, similar policies were adopted by the State Health Departments of these three States in dealing with "phenol," a tar-acid product of the by-product coke industry which was formerly discharged into the streams, causing offensive tastes and odors in public water supplies down stream.

In 1923, H. R. Crohurst, Sanitary Engineer with the U. S. Public Health Service, made a comprehensive study of the damaging effect of phenol on public water supplies throughout the Ohio Basin. Remedial action was taken by the steel industry in one State after another as a common policy was pursued, with the result that to-day in many plants, phenol is reclaimed by the steel industry; it has become a valuable by-product rather than a trade waste. Two cardinal principles of administrative practice in industrial pollution control are illustrated by this experience: (1) The establishment of a common policy over an entire water-shed area in dealing with a detrimental trade waste; and (2) the practice of having the technical man in industry meet the technical engineer in Government service to work out the practical way of eliminating or properly treating the harmful substances discharged into streams.

The experience of State co-operation in dealing with the phenol pollution served as a guide when the question arose some years later as how best to combat the tremendous acid load which was coming into the Ohio and its tributary streams from the bituminous coal mines in Pennsylvania, Ohio, West Virginia, and Kentucky. The Board of Health Commissioners of the Ohio River Basin, a voluntary co-operating group of State Health Officials, authorized the Ohio River Board of Engineers to prepare a comprehensive plan for reducing this drainage. A report was accordingly prepared by the Board of Engineers, at Huntington, W. Va., in October, 1933, and served as a basis for the program of sealing abandoned coal mines, which was inaugurated in December, 1933, and was under the direction of the U. S. Public Health Service. The workers on this project, started under the Civil Works Administration, were unemployed miners and mining engineers. With intermittent spurts and lags, the program has gone on, until now (1937) it is well organized under the Works Progress Administration. The supervisory group of mining engineers in each State is in the employ of the U. S. Public Health Service.

The public health engineers of the States involved co-operate closely with those in the Federal service. The work in each State is under the Sanitary Engineering Division of the State Health Department, for this is primarily a program affecting public water supplies and stream pollution.

The following summary of accomplishments in West Virginia up to July 1 1936, is typical of the project as a whole:

Total number of coal mines in State	2 212
Active mines	613
Marginal mines	241
Abandoned mines	1 358
Abandoned mines sealed to July 1, 1936	405
Number of openings sealed	3 644
Average openings per mine	9

The unit costs were as follows:

Average total cost: Construction per opening	$ 89
Average total cost: Maintenance per opening	16
Total expenditure per opening to July 1, 1936	$ 105

From analyses of more than 2 000 mine-water samples, C. L. Chapman, Field Director for West Virginia, computes that by July 1, 1936, the acid drainage originally coming from the 405 air-sealed mines had been reduced by 51.1 per cent. The original daily acid production of these mines was 467 835 lb.

E. W. Lyon, Regional Director of the Mine Sealing Program, with headquarters at Pittsburgh, estimates that the total acid pollution from all mines (active, idle, and abandoned) in the Ohio Basin amounts to more than 15 000 000 lb per day. The acid load from about two-thirds of all mines—that is, the "abandoned" group—can be substantially reduced by a continuation of the present program. Again it should be pointed out that this work has been made possible by co-operative effort of the States and the Federal Government, and by Federal money apportioned on a regional basis. It is believed that the mine-sealing project is deserving of consideration in any program for water conservation in this basin.

Progress in Developing a "Water-Shed Consciousness"

The third of the "what progress" questions involves something more or less intangible—the development of a "water-shed consciousness." Progress along such lines, of course, cannot be defined quantitatively. It can be stated, however, that "water-shed pollution consciousness" in the Ohio Basin was first aroused in 1924 by the water conservation agreement between the Health Departments of Pennsylvania, Ohio, and West Virginia; and mention may be made of two more recent developments along similar lines.

The Ohio Valley Improvement Association, organized in 1893, has been interested primarily in navigation, but in 1935 it took for the theme of its Annual Meeting the control of pollution and floods on the Ohio River. This organization has been successful in securing the canalization of the Ohio River for navigation, and it is hopeful of being equally successful as it turns its energies to pollution and flood-control measures. Its members, scattered far and wide over Pennsylvania, Ohio, West Virginia, and Kentucky, form the nucleus for an appeal to the citizens and the legislatures of the several States to co-operate in a program of pollution abatement along the Ohio River.

In addition to this organization is a new one, inaugurated in Cincinnati, Ohio, on May 12, 1935, through the untiring efforts of Alfred Bettman, Chairman of the Fifth District, National Resources Committee, and Hudson Biery, Chairman of the Stream Pollution Committee of the Cincinnati Chamber of Commerce. During the winter of 1935–1936 Mr. Bettman called together representatives from the State Planning Boards of Pennsylvania, Ohio, West Virginia, Kentucky, and Indiana to effect, if possible, an Ohio Valley Planning Commission, whose purpose would be to plan for the best uses of the waters of the Ohio Basin for the future. His inspiration came from the findings and recommendations of the report of the Mississippi Valley Committee. A permanent organization was effected on March 12, 1936, with Mr. Bettman as Chairman, with headquarters in Cincinnati. As Chairman of the Stream Pollution Committee of the Cincinnati Chamber of Commerce, Mr. Hudson Biery has been successful in bringing a large number of influential civic organizations in Cincinnati to work in a united effort for an Ohio Valley Planning Commission and, for the enactment of national legislation by the Congress to permit groups of States on a water-shed to co-operate and to formulate a comprehensive plan for dealing with detrimental stream pollution.

Progress in Legislation

The fourth "what progress" inquiry deals with legislation: What progress has been made toward increased Federal and State co-operation in stream-pollution control in the Ohio Basin?

The Cincinnati group realized that a compact must be prepared, adopted by the States, and approved by the Congress before the States could work together effectively on a remedial program. Authorization of a compact by Ohio River States to work together on stream pollution control was given by the Congress in May, 1936. Thus, the ground-work has been prepared for the States to appoint commissioners to negotiate a compact to be adopted by the several State Legislatures. This is no easy task, but it is the beginning of the actual program.

The Ohio Valley is not the only water-shed or basin in the United States where interest in stream pollution is high. During 1936, from New York State and Connecticut, as well as from the Ohio Valley, measures were introduced in the Congress providing for Federal control of stream pollution. Some of the bills in Congress, particularly the Lonergan Bill, were of a drastic nature, but those prepared by the Committee of the Cincinnati Chamber of Commerce were of a more moderate type. One bill provided for a Division of Stream Pollution Control in the U. S. Public Health Service, setting up the machinery for investigating water pollution and preparing a national plan by water-sheds, also for assisting State health departments to establish proper bureaus for stream-pollution control. Another bill provided for control of stream pollution by the United States Army Engineers. Hearings were held on all these bills during March, April, and May, 1936, but none of the measures providing for national control of stream pollution was enacted by the Congress.

The Cincinnati-Louisville group associated with Mr. Bettman has furnished the motivating force to bring to a focus before Congress all the happenings in the Ohio Valley with respect to stream pollution in the past decade. The hearings on the Vinson-Barclay Bill make out a strong case for a moderate type of control, placing in the U. S. Public Health Service the functions of investigation, planning, and recommending action but retaining to the States the active control of stream pollution. This appears to be the wisest type of procedure at the present time.

OTHER FACTORS BEARING ON POLLUTION CONTROL

Mention has been made of the Board of Health Commissioners, Ohio River Basin, which is made up of the State Health Commissioners of States in the Basin. Under authority of this voluntary co-operating group of public health officials, the Ohio River Board of Engineers has thus far carried out the technical work and studies incidental to reducing sewage and industrial pollution within the Ohio water-shed. Certain points were stressed in the engineering report dealing with sanitary conservation of the water resources of the Ohio River Basin made to Mr. Bettman on January 18, 1936, which are worthy of mention. The engineers listed the priority of uses of the Ohio River in general as follows: (1) Public health; (2) drainage; (3) navigation; (4) industry; and (5) recreation.

Among general remedial measures, two important points are stressed: "Interlocking factors" and "low-water control." The following quotation is from that report:

"*Interlocking Factors:* Improving the sanitary condition of the Ohio River in a way best serving the public interests is not confined merely to the treatment of pollution, which, in fact, is only one of the elements of a comprehensive plan. In the past such problems were approached from a single viewpoint. But the Water Resources Board have clearly shown in their reports the interrelation of other factors 'to secure the greatest total benefit from the natural resource,' and, on the other hand, to make the cost of each component benefit less than it otherwise would be.

"As to sanitation, the chief factors are (1) adequate purification of public water supplies, (2) the interception and treatment of sewage and industrial wastes, (3) reduction of acidity, (4) low water control, (5) construction and operation of navigation works, and (6) the malign or beneficial influence of tributaries.

"*Low Water Control:* Streams in a natural state are subject to a wide range both in stage and discharge because of the wide variation in rainfall. So far as sanitation is concerned the low flows of summer are the critical times for stream pollution of organic origin, because of lack of diluting water and high temperatures fostering decomposition. Ofttimes quite expensive treatment plants are required to prevent harmful pollution during such critical times. Therefore, means for augmenting these natural low-flows make possible economies in the treatment of pollution.

"In accordance with Document 308, U. S. Army Engineers, and other authorizations of the Sixty-Ninth Congress, many studies have been made for flood control reservoirs and some of these have been designed for low water control, that is to say, for the retention in the reservoir of sufficient water to be released for augmenting the low flows of the stream below, which will be a material benefit to the sanitary condition of the streams. For example, the reservoir now being built by the Federal Government on the Tygart River in West Virginia is said to be intended to release three hundred and forty cubic feet per second of water from July to December. During extreme drought the unregulated Monongahela River below this reservoir has reached a condition of almost no flow. Where, in the public interest, it is practical so to do, flood control reservoirs in the Ohio River Basin should be designed to provide for low water control. One reason is the actual economies in the reduced cost of treating sewage and industrial wastes, and the other, and possibly higher but intangible benefits, through the resulting protection to the public health. Low water control is an important factor in sanitary improvement of the Ohio River and its tributaries."

SUMMARY

Progress in stream-pollution control in the Ohio River Basin may be summarized as follows:

(1) Beginning with the co-operative movement between State Health Departments in the Basin in 1924, a "water-shed consciousness" was awakened. The most recent development is the organization of the Ohio Valley Planning Commission, which is working under the auspices of the National Resources Committee.

(2) New sewerage systems and sewage disposal plants to the value of $12 000 000 have been built with funds jointly provided by the Federal and City Governments in the period, 1933–1936. This represents about 20% of the total expenditure necessary to afford primary treatment to all sewage along the river.

(3) The U. S. Public Health Service and various States in the Basin are carrying on a joint program to reduce the tremendous pollution caused by acid drainage from abandoned mines. A reduction of more than 50% in acid drainage is reported from the mines already sealed. The present program is financed through the Works Progress Administration.

(4) Legislation was enacted by Congress in 1936 providing for a compact between States on the water-shed, with respect to pollution control and other water conservation measures. It is hoped that ultimately an interstate compact will be drawn up and ratified. Hearings have been held in Congress on proposed bills providing for Federal control of stream pollution, and it appears likely that a moderate bill, involving co-operation between State and Federal authorities, may be passed in the near future.

PLANNING FOR POLLUTION CONTROL AT PITTSBURGH, PENNSYLVANIA

By D. E. Davis,[15] M. Am. Soc. C. E.

Synopsis

Pittsburgh's rugged topography creates a complicated sewage disposal problem. The heavy acid load in the rivers, largely from mining operations, inhibits bacterial growth, prevents a major nuisance, and postpones the attack on the disposal problem. Primary treatment plants are indicated as meeting the requirements for a considerable period; and sites are available which will avoid the expense of costly interceptors and tunnels. River transportation can be used for conveying sludge to a central plant for final disposition.

Decided economies in first cost and in operation can be achieved if the 116 interested municipalities join forces. Public sentiment would probably support a "clean-up" program; but enabling legislation will be required.

Competent authorities have stated that the rugged topography of Greater Pittsburgh, or Allegheny County, Pennsylvania, and its multitude of governmental jurisdictions, create one of the most complicated sewage disposal problems in the United States. The Allegheny River flows from the north 30 miles, and the Monongahela River from the south 35 miles through the rugged and precipitous hills of Allegheny County to form the Ohio River, which flows westerly another 15 miles before leaving the County. Along these 160 miles of shore line are 116 separate municipalities with a total sewered population of approximately 1 200 000, representing one of the most highly industrialized sections in the country, sometimes called the "Ruhr of America."

Although most of these communities are sewered, there is comparatively little treatment of the sewage, most of which enters the stream in its raw state. To this untreated sewage are added industrial wastes with a population equivalent estimated by the U. S. Public Health Service to be nearly as great as the actual human population of the area. This pollution, at times, exercises harmful effects down stream, such that for considerable periods the bacterial counts at East Liverpool, Ohio, Steubenville, Ohio, and Wheeling, W. Va. (and in the Ironton-Portsmouth District, in Ohio, possibly affected in part by the sewage of Pittsburgh) are among the highest in the country. Commenting on this situation, H. R. Crohurst, Senior Sanitary Engineer in Charge, U. S. Public Health Service at Cincinnati, has stated:[16]

"Only by constant and efficient supervision of plant operation has it been possible to procure a water of the desired bacterial quality with the rapid changes in raw water. While it has been possible up to the present time to produce satisfactory water supplies from the upper part of the Ohio River in spite of the excessive pollution, for the reasons as outlined urban population and sewage pollution will in a comparatively short time increase to the point where it will be impossible, with all present known methods of water treatment, to produce at all times a water safe for domestic use in these downstream communities."

---

[15] Engr. (The Chester Engrs.), Pittsburgh, Pa.

[16] Unpublished report.

Estimates indicate that a flow of approximately 9 000 tons of acid (as pure sulfuric acid) passes Pittsburgh daily, which causes economic loss to steel barges, pipe lines, concrete work, and other structures subject to acid attack. The Monongahela River is highly acid most of the time and the Allegheny River (up to Freeport, Pa.) much of the time during the summer.

It would appear, therefore, that there is a condition requiring early and urgent consideration; and that if steps are to be taken to clean up the Ohio River and its tributaries, Greater Pittsburgh, at the head of the river, should be one of the first communities to place its filth under control.

Early Pollution Studies

Although there is evidence that the general public is becoming increasingly interested in a general clean-up program, it has not yet evidenced its concerted intention to act. However, its representatives in the various State and National Health Departments have been alive to the problem, and as early as 1910 the Pennsylvania Health Department ordered Pittsburgh to present a report on a plan for disposing of its sewage. This report was prepared and presented in 1912, and was followed in 1916 by the classic report of the U. S. Public Health Service on "A Study of the Pollution and Natural Purification of the Ohio River." Again, in 1931–1932, this Service co-operated with the Health Departments of the various States along the river in the conduct of a similar co-operative study of pollution, the results of which are not yet published. In February, 1936, the Ohio River Board of Engineers enunciated the following policy:

> "Every sewered municipality of reasonable size should have a comprehensive plan of sewerage approved by the State Health Department and should diligently proceed, within limitations of financial ability, to construct the intercepting sewers. The larger communities, and those situated within harmful influence of water works' intakes, should be the first to install treatment works to effect at least efficient removal of settleable matter. Thereafter, but as soon as possible, the smaller municipalities should do likewise."

When, in 1933, Federal funds were being made available for various local projects, W. L. Stevenson, M. Am. Soc. C. E., Chief Engineer of the Pennsylvania State Department of Health, urged on the officials of the City of Pittsburgh the desirability of a study of its sewage disposal problem. As a result, the Metropolitan Drainage Survey was initiated under the general direction of Charles M. Reppert, M. Am. Soc. C. E., Chief Engineer of the City of Pittsburgh, and continued under his successor, Henry D. Johnson, Jr., Assoc. M. Am. Soc. C. E. Although the population embraced within the City of Pittsburgh proper represented about one-half that in Allegheny County (or Greater Pittsburgh), it was realized that it would be inexpedient for the City to attack its problem independently, without knowledge of its effect on the county-wide situation; and that in any case it should have a picture of the problem in its entirety and the City's relation thereto. Consequently, the study covered the entire County or Metropolitan Area.

The report of 1912 had not been wholly fortunate in its reception, since it had left the impression that the costs of sewage disposal were excessive. Its study was based on "considering only those methods which will be reasonably efficient and certain in stopping the passage of infectious matter." Estimates were prepared for separate sanitary sewerage systems for all river communities within Allegheny County (above Neville Island, Pa.), and for long interceptors and tunnels terminating in a pumping station delivering to a central complete treatment plant on Neville Island, about six miles below the "Golden Triangle." The total cost for Pittsburgh was estimated at $37 300 000, and for the County as a whole (above the Island) at $57 000 000, which, in terms of present-day prices, would be at least doubled. Naturally, this huge cost imposed an effective brake on affirmative action.

THE METROPOLITAN DRAINAGE SURVEY

Since 1912 material changes have altered the aspect of the problem. The use of combined sewers in handling dry-weather domestic sewage flows is better understood and more commonly practiced; the rivers are more completely canalized; Neville Island is now largely occupied by industry, and hence not available as a sewage plant site; acid waste discharge has increased; and the Health Department Engineers now consider simple primary treatment of sewage as being generally adequate, at least as the first step in the clean-up program. These changed conditions counseled a completely fresh approach to the problem.

In assembling the fundamental design data for the new study, it was decided to adopt drainage basins as the basic units without respect to their relationship to administrative areas. The population within these basins was rather accurately determined from the small Census Districts, and from the past trend in each basin the population in 1970 was predicted; a correlation between water pumpages and sewer weirings in typical sewers supplied information as to probable sewage flows; and field surveys were made of possible plant sites and intercepting sewer locations.

INFLUENCE OF ACID ON NATURAL PURIFICATION OF STREAMS

Concurrently, studies of the bacteriological and chemical conditions in the rivers were undertaken to determine the degree of treatment which might be required at different times of the year, and under varying conditions; as well as to develop a standard by which the degree of improvement provided by future plants might be measured. A problem special to this area was posed by the relatively large acid content of the streams and its marked effect on the process of natural purification in the rivers. It was found that the acid appeared to inhibit and postpone the normal processes. Although this action was locally beneficial, minimizing nuisances that might otherwise be expected to occur, it did not eliminate the offensive organic matter, but merely transferred it down stream for the resumption of normal processes in the reaches where alkaline conditions were restored in the river.

Naturally any change in the acid content by dilution water from the new flood-control reservoir on the Tygart River, or from others to be constructed later, or by acid elimination through mine sealing, might have a marked effect on nuisance conditions at Pittsburgh. A comparison between the Pittsburgh and the Cincinnati-Louisville observations, for 1914 and 1930–1932, yielded valuable information as to the effect of acid on the inhibition of self-purification, and of the degree with various concentrations. Except for the amount of acid and the quantity of flow, the conditions in these two districts are substantially similar, since the rivers are fully canalized and the effects of sedimentation in these enormous settling basins are somewhat alike. Table 5 indicates the marked differences in the condition of the river water in the two districts for low-flow periods.

TABLE 5.—Comparison of River Conditions Immediately Below Pittsburgh, Pa. (1932) and Cincinnati, Ohio (1930)

(Results expressed as monthly averages)

Month	Stream Flow, in Second-Feet		Methyl Orange Alkalinity, in Parts per Million		Five-Day Bio-Chemical Oxygen Demand, in Parts per Million			Dissolved Oxygen, in Parts per Million		*B. Coli* Index per 100 Cubic Centimeters	
	Pittsburgh*	Cincinnati	Pittsburgh†	Cincinnati	Pittsburgh†		Cincinnati	Pittsburgh†	Cincinnati	Pittsburgh†	Cincinnati
					Calculated	Actual					
September	1 610	4 830	3.4	66	35	0.2	3.5	0.8	2.2	345	160 000
October	2 940	3 360	4.5	78	19	1.2	4.0	4.9	2.94	237	415 000
November	18 900	5 570	10.7	72	3	3.1	5.5	10.9	7.58	8 970	1 441 000

* Seven miles below the confluence of Monongahela and Allegheny Rivers.

† Three miles below the confluence of the Monongahela and Allegheny Rivers.

The following quotation from a report[17] by Mr. Crohurst indicates what might be expected if the acid were largely eliminated so that the rivers at Pittsburgh would become alkaline:

> "With possibly twice the equivalent sewered population at Pittsburgh and much lower flows than at Cincinnati, it is believed that the dissolved oxygen would (in Sept. to Nov. 1932) have been entirely depleted in and below Pittsburgh for a considerable distance, if normal river conditions unmasked by excessive acidity had existed."

Under such conditions it is probable that the stench would be so vile that the public would then demand sewage disposal for relief. It seems fair to conclude that if acid is materially reduced during low-flow periods, nuisance conditions will unquestionably develop.

---

[17] Unpublished report.

EFFECT OF SLUDGE ON DOWN-STREAM WATER SUPPLIES

The U. S. Public Health Service report also emphasized the fact that the critical period for down-stream water plants is that immediately following a rise in the river with velocity sufficient to scour out accumulated sludge banks. At such times there is a precipitous increase in bacterial counts, and the pollution load on the down-stream plants becomes excessive. The minimum effective program of sewage treatment would be that afforded by primary sedimentation plants, which would remove the settleable solids now forming the sludge banks. At the same time this would prevent local nuisances, and remove the wave or "slug" of pollution which now moves down river with freshets. The general clean-up plan was based on the construction of primary plants as being adequate for present requirements.

PHYSICAL ASPECTS OF PROPOSED TREATMENT PLAN

The development of the physical aspects of the plan was largely dictated by the unusual topography of the district. Recalling the 160 miles of shore line, it may be realized that if an effort were made to concentrate the sewage at relatively few sites, the costs of interceptors and pumping stations would be enormously expensive. Most of the communities in Allegheny County extend up the hillsides back from the rivers, and their major sewers traverse the valleys of minor streams to their outlets in the rivers. Surveys revealed that sites could be found at or near the mouths of many of these streams, and that the problem could be solved by the construction of not to exceed thirty-six plants. Further study may show that this number can be somewhat reduced.

Primary treatment plants would incorporate mechanical screens, sludge grinding, detritors, plain sedimentation with mechanism for gathering the sludge, pumps, sludge digestion tanks, and provisions for chlorination, when and if necessary. At a comparatively small increase in cost, chemical treatment could be added and peak-load conditions met, should experience indicate the need. Sludge beds would be eliminated at the individual plants in the interest of economy in construction and operation, as well as for the conservation of expensive space. The digested sludge would be delivered by gravity directly to barges (similar to those now in use for transporting gasoline) at loading docks adjacent to the plants, for delivery to storage tanks at a central sludge disposal plant equipped with vacuum drying and incineration facilities. Ample storage would be provided both at the individual plants and at the central plant, so that the barge fleet could be removed from service during two or more months in the winter when the rivers might be partly covered by ice, and to permit vacations and fleet repairs.

ECONOMIES IN COUNTY-WIDE PROGRAM

The necessary interceptors, diversion and control chambers, pumping stations, treatment plants, barge fleet, and central sludge disposal plant, to afford primary treatment for the sewered communities along the three main rivers and their minor tributaries in Allegheny County, can be constructed for less than $20 000 000. The possible reduction in number of plants, by re-grouping, in the interest of reduced operating expenses, might affect this estimate; but in a general way it serves to fix the scale and magnitude of the task. Decided economies are made possible by approaching the problem on a county-wide basis; for the low-cost river transportation of sludge can thereby be taken advantage of, and the single sludge disposal plant can be made available at a fraction of the cost of equivalent facilities provided by each community on its own responsibility. Moreover, the cost of a few large primary treatment plants, each serving an entire drainage basin, is less than that of a multitude of small plants, each serving a separate community. The project lends itself to unified direction and group operation, making possible expert technical supervision that, on a shared basis, will be better in quality and lower in cost than would likely be possible to individual municipalities.

The studies indicate that the proposed method of treatment would increase the oxygen content of the river at all times and would remove the danger of an oxygen deficiency at Pittsburgh. (Such a deficiency existed for a short period during the 1930 drought.) It is believed that this degree of treatment should suffice for an extended period. If secondary treatment should later be found advisable, the primary plants could continue to function as such; and a number of secondary treatment works could be provided, each of which would handle the pumped effluent from a group of primary units. There are six prospective sites, scattered over the area, which, in their present state of development, would prove acceptable locations for such secondary plants.

Such an expenditure ($20 000 000) is not an unreasonable price to pay for sewage treatment at Pittsburgh, in view of the benefits that it would confer—the removal of foul local nuisances, the reinstatement of river recreation as a relatively safe diversion, and the "good-neighbor" service of improving the quality of the raw river water for down-stream communities. By way of comparison, it may be pointed out that the estimated cost of sewage purification is about four times the cost of the George Westinghouse Bridge and its approaches, and about one-fourth the sum that would be necessary for reproducing the water-works systems in Allegheny County.

The Problem of Stimulating Public Interest

It is one thing to indicate the nature and extent of a problem and the means to its solution, but it is quite another matter to bring it to execution. The need is present, and the practical question turns on the best way to achieve the desired clean-up. It is obvious that without the whole-hearted approval of the general public, little can be accomplished. The first job is to overcome the apathy of the electorate and to carry home the realization that civic morality requires that communities dispose of their waste products without endangering health, or occasioning undue financial burdens on their neighbors below.

Time was when the drinking of unfiltered water was the general rule, and water-borne disease stalked the land. The great majority of filtration and water purification plants in the United States have been built within the easy recollection of men now in their prime. When the public became convinced that the dreaded typhoid fever was a water-borne disease, potentially affecting the health of each member of the community, it did not require much argument to develop the conviction that pure water was cheap at any price. The small increase in the water rates was much less than the ever-possible doctor and hospital bill. This was personal knowledge and elementary financial common sense.

The case for sewage purification, however, is not made out so easily. Many communities are not moved to the building of disposal plants until threatened with damage suits by lower riparian owners; then it becomes a nice calculation as to whether it is cheaper to build a plant than to pay damages. Few communities treat their wastes solely for the altruistic purpose of bettering the river for the water plants of communities below. They have projects that are much nearer their hearts and pocket-books—school houses for their own children, better streets for their personal automobiles, and bridges for streams which they themselves must cross frequently, are tangible goods whose benefits are obvious to those who pay the bills. Until these pent-up demands have been at least partly satisfied, the voter can hardly be expected to be enthusiastic about the disposition of his waste products unless they assail his nose or threaten his bank account. However, there is much evidence to the effect that these insistent needs have now been pretty generally satisfied in most communities, and if (as is predicted), the growth in population should soon slow down or even cease, the usual outlets for public moneys may dry up, and funds may be available for projects previously regarded as luxuries.

Increasing leisure for healthful outdoor pursuits should stimulate interest in cleaner streams. Fishermen are not greatly interested in cleaning up streams in some other taxpayer's county, but if they could be brought to realize that fishing could be made good in their own vicinity, they might be more willing to loosen up on their own purse strings.

The rivers here under discussion flow through a territory peculiarly devoid of lakes. However, the Ohio River and its main tributaries are fully canalized, and during low-flow periods in the summer are to all intents and purposes long inland lakes, whose waters are usually quite clear. Under Health Board control, they would lend themselves admirably to water diversions of all kinds, were the conditions more propitious. Bass could be caught at Pittsburgh less than forty years ago, and if the conviction and fear of disease were not generally prevalent, it is probable that the streams would be alive with recreational enthusiasts. Wind currents are known to carry the sewage of some communities past their own water-works intakes, thus placing an undue load on water purification processes. These are all valid arguments for affirmative action, and there is good reason to believe that the public might be appealed to on grounds of its own self-interest as to the value of clean streams. The first job then is to convince the public of its obligations, the honoring of which will yield dividends in health and recreation.

The absence of fish in the Upper Ohio River is very largely attributable to acid wastes, mostly from abandoned mines. The responsibility for its removal is obviously that of the State and National Governments. The mine-sealing program now in progress in the Ohio River Basin gives promise of a material reduction in this highly objectionable waste.

Co-operative agreements between industries and State Health Departments have been effective in setting up research programs within the affected industries, looking to the profitable reclamation of by-products which formerly polluted the streams. These programs should be expanded, but, in addition, legislation similar to the Lonergan or Barclay Bills should empower the policing of recalcitrant industries. Preferably this clean-up should be on a broad geographical basis, so as not to impose unfair competitive burdens on industries complying in good faith.

Sewage Disposal a Municipal Responsibility

The disposition of human wastes, which represent the preponderant source of pollution, is squarely up to the various communities. It is apparent that in the Pittsburgh District, the most economical and only practical way of accomplishing this result is by bringing all the communities together in a co-ordinated body, such as a sanitary district. This will require enabling legislation, since the job of coaxing voluntary co-operation among 116 separate jurisdictions is humanly out of the question. A few communities have worked out joint compacts for the construction of intercepting sewers, but the negotiations covered an extended period and the method proved unwieldy in the extreme, and would not apply to Allegheny County as a whole.

In 1927, the Pennsylvania Legislature passed a bill permitting a "Metropolitan Plan" for Greater Pittsburgh, embracing Allegheny County as a whole. Had this been adopted, it would have provided for numerous projects which would lend themselves advantageously to joint effort in their execution. However, it failed of ratification on the two occasions when it was presented to the voters. The 1935 Legislature passed a Municipal Authority Act with the intent of permitting somewhat more liberal methods of financing than those now available, so that many governmental jurisdictions could participate in improvements by accepting the financial co-operation of the Federal Government. This would have permitted the issuance of revenue bonds and the assessment of charges for service rendered (such as sewer rentals), but the provisions as to new projects terminated in 1937, without any action having been taken.

There is no reason to believe that the Legislature cannot provide means for creating the necessary machinery for advancing a unified program. The minimum provisions should incorporate joint ownership of the facilities, power of compulsory assessment (preferably of sewer rentals) for construction and operation by the central representative executive group, the right to issue revenue bonds, and preferably a provision for administration on a Civil Service basis.

Conclusion

The Pittsburgh study indicates that the rivers in its vicinity can be cleaned up at a reasonable cost for initial construction and for operation. It is believed that on a fair presentation of the problem, the public may be prepared to sanction an adequate disposal of its sewage, and that the requisite legislation may be had to effect this result.

STREAM POLLUTION PROBLEMS AT CINCINNATI, OHIO

By J. E. Root,[18] M. Am. Soc. C. E.

Synopsis

The nuisances created by sewage and industrial wastes as they have affected the condition of the Ohio River have been under observation since 1908. From time to time remedial measures have been recommended. Due to the fact that the river for the most part is the boundary line between a number of States, a correction of the pollution problem will require the joint co-operative action on the part of these States, or a number of them. Complete canalization of the Ohio River further complicates the problem, as do floods and extreme periods of low flows. The paper for the most part deals with river conditions within the Cincinnati Metropolitan Area.

Pollution of the Ohio River has received almost continuous public attention since 1908, when the subject was first investigated by a Joint Ohio River Sanitary Commission composed of representatives from Pennsylvania, West Virginia, Kentucky, Ohio, and Indiana. The general conclusion of the 1908 and 1909 investigations[19] was "* * * that the Ohio River is generally of objectionable appearance, is frequently very turbid, carries high color in the fall, and must be purified before being used for public water supplies." The river water was found to be "grossly polluted at many points along its course," and it was stated that the pollution was becoming more pronounced and more dangerous to the health of the inhabitants of Ohio River cities. A resolution, adopted at a meeting of the Joint Commission on December 1, 1909, recommended that the various municipalities along the Ohio River using the river as a source of water supply take immediate measures to discontinue the discharge of unpurified sewage into the stream.

Early Investigations

For the City of Cincinnati, J. W. Ellms, M. Am. Soc. C. E., as Superintendent of Filtration at the Water-Works, in 1910 and 1911 investigated the condition of the Ohio River water from the water-works intake up stream from the city proper to Fernbank Dam, about 20 river-miles down stream from that point. As to the effect of the sewage from the Metropolitan Cincinnati area upon the general quality of the Ohio River water and the influence of the Fernbank Dam, when in service, upon the water, Mr. Ellms summarized[20] in part:

---

[18] Director of Public Works, City of Cincinnati, Cincinnati, Ohio.

[19] Rept. of the Commissioner of Health, State of Pennsylvania, 1909, Pt. II.

[20] Rept. on Investigation of Ohio River at Cincinnati, Seventy-Second Annual Rept. of City Water Works Dept., City of Cincinnati, Ohio.

"The quality of the Ohio River water entering the Cincinnati intake is subject to considerable variation, showing the greatest degree of contamination during flood periods.

"In general, the water at the intake was of better quality during the period the Fernbank Dam was in service than for the most comparable period of low water in 1911 preceding its completion.

"An exception to the above general statement is required for a brief period during which the dam was in service, because of a sudden rise in the Little Miami River, which, in discharging large volumes of water into the Ohio, retarded the flow of the latter, and even produced a back flow of water toward the intake, temporarily causing an inferior and somewhat more contaminated water to pass into the intake.

"The present contaminated condition of the Ohio River water which passes into the Cincinnati intake, whether under normal or abnormal conditions, need not be feared by consumers so long as the present purification plant is carefully and efficiently operated, since the river water can be clarified and purified and rendered a perfectly safe drinking water by the processes employed."

During July, August, September, and the first week of October, 1911, J. A. Cravan, Water Chemist of the Indiana State Board of Health, made a sanitary survey of the Ohio River between the Ohio State line and the Illinois State line, a river distance of 360 miles. In general, Mr. Cravan's investigation[21] indicated:

"(*a*) That the dissolved oxygen in the river water is not progressively depleted from Cincinnati to the Illinois State line.

"(*b*) That the bacterial content of the water between the same points is not materially higher than at the Cincinnati Water Works intake.

"(*c*) That the river water soon recovers a substantial proportion of the dissolved oxygen lost in its passage through the Cincinnati pool."

Under the direction of Henry M. Waite, M. Am. Soc. C. E., City Engineer of Cincinnati during 1912 and 1913, as part of a comprehensive plan of sewerage for the city, studies were made for sewage treatment and disposal, and a system of intercepting sewers was developed with outlets that could be adapted to a number of possible plans for sewage treatment. The problem of sewage treatment and disposal was investigated by the late Harrison P. Eddy, Past-President and Hon. M. Am. Soc. C. E. His report,[22] entitled "Report upon Necessity and Feasibility of Treating the Sewage of Cincinnati Before Its Discharge into Ohio River," was filed with the City in the latter part of 1913. Mr. Eddy based his studies of the problem upon two main considerations:

"*First.*—Consideration of the character of the water as it reaches Cincinnati, and the effect of the sewage and wastes discharged into the river above the city.

"*Second.*—The effect of the sewage discharged by the cities and towns in the immediate vicinity of Cincinnati, herein designated the Cincinnati District."

The general conclusion of the report may be summarized in the following quotation:

"In view of the fact that it does not appear that sewage treatment will be necessary at Cincinnati for a number of years, it does not seem wise to recommend any specific method of treatment or that any site be secured for a treatment plant. Methods of sewage treatment have been improved, and new methods have been devised during recent years, and much further improvement may reasonably be expected during years to come. It would, therefore, seem idle to take steps at this time which would commit the City of Cincinnati in any way to a particular method of treatment. It is necessary and wise, however, to so plan and lay out the system of intercepting sewers which may be built from time to time that they may be brought together in harmony with any method for the treatment of sewage which may be adopted; and should it later prove advisable to intercept the sewage along the Ohio River, before a sewage treatment plant is needed, the site on which such a plant is to be built should then be selected so that the intercepter may be laid out with a view to conveying sewage to that site.

---

[21] Indiana State Board of Health (unpublished).

[22] Rept. on a Plan of Sewerage, City of Cincinnati, 1912–1913, p. 295.

"From these investigations, the conclusion is that Cincinnati is not at present justified in going to the expense of building and operating a sewage treatment plant, since the benefits derived therefrom would not be commensurate with the expense."

From July, 1913, until December, 1916, the Ohio River was subjected by the U. S. Public Health Service to special study as a type of large inland river presenting a complex and difficult problem in the control of sewage pollution. The purposes of this study[23] were:

"(1) To give a quantitative statement of the pollution of the river in important zones, as existing at the time of the study, with such evaluation as possible of the relative importance of individual sources or units in contributing to this pollution, and of the relation of the conditions to the public health.

"(2) To furnish the basis for estimating with reasonable precision the changes in status of pollution which may be expected in the future to result from a given change in one or more of the factors concerned; as, for example, from a given increase in the various units of population, or from a given reduction in the polluting effect of their sewage by artificial treatment; or from changes in the velocity of flow, due to the construction of additional dams, as now projected, for improvement of navigation.

"(3) To investigate the possibility of establishing definite quantitative relations between the intensity of pollution, as measured by various laboratory tests, and such obvious factors as are readily determinable by field surveys. Especially has it been the purpose, in this connection, to make a quantitative study of natural purification as related to time of flow, temperature, and other determinable factors of presumptive importance."

THE RE-SURVEY OF 1930

At the time this study was made seventeen of the proposed fifty navigation dams were completed and in operation. Dam No. 37 of the series, at Fernbank, forms the Cincinnati pool. After complete canalization of the Ohio, the U. S. Public Health Service made a re-study[24] during 1930 of that section of the stream between Dam No. 36 (above Cincinnati) and Dam No. 43 (about twenty miles below Louisville, Ky.), a river length of about 164 miles. The re-study was to determine:

"(1) The extent to which the normal increase in population and changes in industrial activities during the intervening 15 years would be reflected by changes in the sanitary condition of the stream as indicated by differences in the chemical and bacteriological findings.

---

[23] "A Study of the Pollution and Natural Purification of the Ohio River," U. S. Public Health Service *Public Health Bulletin No. 143.*

[24] *U. S. Public Health Bulletin No. 204.*

"(2) The effects of canalization during periods of high water temperature and low stream discharge when the sewage and wastes flowed through a series of pools below the points of discharge.

"(3) The present sanitary condition of the river, making possible a comparison of probable conditions in 1930 as forecast by the data collected in 1915, with conditions as they actually existed in 1930.

"(4) Possible differences in the rates of chemical and bacteriological changes indicated by the two sets of observations as a result of changes in the amount and character of the pollution and in channel conditions."

The effect of canalization, as indicated by the re-study, is summarized in the following quotation from the printed report:[24]

"Canalization, at least between Cincinnati and Louisville, has had a tendency to complicate rather than simplify the problems connected with sewage disposal, possible nuisance production, the operation of water-treatment devices, and the preservation of the public health."

POLLUTION CONTROL REQUIRES CO-OPERATIVE ACTION

Parts of fourteen States lie within the Ohio River drainage area. The drainage area above or to the east of Cincinnati is approximately 76 300 sq miles, or slightly less than one-third the total area of the basin. When the Ohio River leaves the State of Pennsylvania it forms the boundary line between the States of Ohio, Indiana, and Illinois on the north, and the States of West Virginia and Kentucky on the south. To correct a bad condition along this river, such as pollution, therefore, becomes an inter-state problem. Actually, all the States in the water-shed share a responsibility and are contributors toward the creation of this undesirable river condition. Since 1935 considerable public agitation has developed demanding that proper corrective measures be taken. These demands were presented to the Second Session of the Seventy-Fourth Congress, with the result that in June, 1936, a Joint Resolution was passed enabling certain States—including Pennsylvania, West Virginia, Kentucky, Indiana, Illinois, Tennessee, and Ohio, or any two or more of them—to negotiate and enter into agreements or compacts for conserving and regulating the flow, lessening flood damage, removing sources of pollution of the waters thereof, or making other public improvements on any rivers or streams whose drainage basins lie within any two or more of the specified States.

Since the passage of the Federal resolution, a number of the States have arranged for and appointed Commissioners to meet jointly with Commissioners from the other Ohio River States. At the present time (1938), therefore, there is in the making the possibility of joint State action which may eventually lead to definite plans for pollution control.

Whatever the problem of stream pollution may be for Cincinnati, the measures required for its correction cannot be accomplished by the City of Cincinnati acting by itself; for the Metropolitan District consists of a number of politically independent incorporated cities and towns—about twelve north of, and ten south of, the river. The problem calls for inter-city as well as inter-state co-operation. Conversely, what the City of Cincinnati does or fails to do which may result in the creation—or, more correctly, the re-creation—of the pollution problem in the Ohio River is the co-operative negligence of a large metropolitan district with a total population of approximately 700 000, of which number approximately 470 000, or about 70%, are within the corporate limits of the city.

Each investigation of river conditions, from the first in 1908 to the most recent in 1930, established the fact that the Ohio River on its arrival at the eastern edge of the Metropolitan District was a polluted stream. In part, therefore, the conditions at Cincinnati are the result of negligence on the part of others up stream, not only on the Ohio River proper, but on practically all its tributaries; and an equitable solution for the problem at Cincinnati must pre-suppose that equal corrective measures will be taken on the part of those responsible for the polluted condition of the water as it enters the district.

The Effect of Canalization

Canalization of the Ohio River has intensified the pollution problem. The Cincinnati pool is created by Dam No. 37, located at approximately the most westerly corporation limits of the city. This pool extends twenty miles up stream to Dam No. 36, which is approximately at the most easterly corporation limits of the city. The business or central district of the city is about equi-distant from the two dams, and on the Kentucky side, the center of the developed area is at about the same point. Maximum pollution, therefore, occurs in the river near the central section of the city as well as of the Metropolitan District.

For navigation purposes the crest of Dam No. 37 is at such elevation that a minimum stream depth of 9 ft obtains at the easterly end of the pool. A rough estimate of the quantity of water in this pool at a time of zero velocity, is 16 000 000 000 gal. During periods of continued dry weather the minimum quantity of stream flow at times may be less than 3 400 cu ft per sec. For five months—July to November, 1930—during an investigation made by the U. S. Public Health Service, the average monthly stream flow was 5 000 cu ft per sec. The time required for water to pass through the Cincinnati pool, at periods of minimum discharge in 1930, was on the average 56.6 hr, or more than $2\frac{1}{3}$ days. For the extreme minimum monthly average stream discharge (October, 1930) it was estimated that the time required was in excess of 100 hr, or more than $4\frac{1}{6}$ days. At times of low flow, therefore, the pool acts as a receiving and settling tank for the sewage and the industrial and commercial liquid wastes from the Metropolitan District; and decomposition soon takes place and offensive odors are produced. There are extended periods during the summer and early fall months when the pollution from the Metropolitan District has a marked effect on the river at Cincinnati, and at such times the dissolved oxygen in the water has sometimes been completely exhausted.

Other Factors

The selection of possible sites for sewage treatment works will be no small problem. The Ohio River channel within the Metropolitan Area, is of comparatively recent geological origin. It is narrow, its banks are steep, and there are few low areas of sufficient acreage to accommodate works of the character required. When the comprehensive sewerage plan was investigated in 1912 and 1913, just five locations were considered suitable for treatment plant works. Since then the new Cincinnati Union Terminal has taken possession of one of the areas, and the Municipal Airport has acquired a second. Moreover, one of the remaining locations is near the Great Miami River, about sixteen miles from the central section of the city. To take care of the pollution on the Ohio side of the river, at Cincinnati, would require works costing approximately $15 000 000.

Another factor requiring thoughtful consideration as a part of the pollution problem is that of floods in the Ohio River. The U. S. Weather Bureau Office at Cincinnati has records of river stages from June 1, 1858, to date (January 1, 1938). In this 80-yr period, the maximum flood height was slightly less than 80 ft (79.99 ft at 4 A.M. January 26, 1937); the next highest flood reached approximately 71 ft (February 15, 1884, 71.06 ft); and the third highest was just under the 70-ft stage (69.8 ft, April 1, 1913). The records indicate twelve floods of 60 ft or more during the eighty years, or an average of one such flood every seventh year. To the city, the physical effects of flood waters begin to be felt at an elevation of about 50 ft. Such a flood may be expected to occur once every sixteen months.

CONCLUSION

In conclusion, it may be stated that the Metropolitan District, of which Cincinnati is the largest urban area, realizes that the Ohio River during six months of the average year is grossly polluted. To correct, in part or wholly, this unfavorable situation will require joint action by many incorporated municipalities within the Metropolitan District, as well as by the States of Ohio and Kentucky. It is realized, also, that the possible solution of the problem will be critically affected by two extreme factors—low dry-weather flows and high flood flows. The works required will cost many millions of dollars to construct, and no mean sum annually for satisfactory operation.

WHAT CAN BE DONE ABOUT STREAM POLLUTION?

By Abel Wolman,[25] M. Am. Soc. C. E.

Synopsis

The elements of the stream-pollution problem are reviewed. The possible results of activity in the fields of law, science, finance, and administration are briefly evaluated. The key to present difficulties appears to be primarily in raising money for corrective measures. Opportunities in State or Federal subsidies or grants-in-aid are emphasized.

The revival of interest in the control of stream pollution is one of the significant trends in the field of water resources control. In earlier days, navigation caught the public eye and for many years dominated the scene in opening up the country. Emphasis then shifted at a later date to flood control.

One of the national results (and incidentally one of the penalties) of population and industrial growth appears in the present emphasis on the correction of stream pollution. To sanitary engineers, particularly those engaged in health department practice, this emphatic public interest is somewhat of a curiosity, since for several decades one of the primary concerns of health departments has been the prevention and alleviation of stream pollution. The diagnosis of the causes for this recent and dramatic interest of the public in this field would offer in itself an attractive field for research.

As in all matters of public concern, the answer to what can be done about stream pollution will depend upon the experience, training, temperament, and prejudices of individuals. Those who have had least to do with the problem are prone to over-simplify the solutions, while those who have struggled with the issue for a great many years are accused of delaying the wheels of progress by being too lax in the enforcement of laws and not active enough in public education. Solutions are offered in law, in science, in finance, and in administration. What are the probabilities of success in each of these fields?

Before attempting to analyze these probabilities, a few general facts should be considered.

The intensity of stream pollution is not nation-wide. It is concentrated largely in five or six of the heavy industrial States. Population distribution alone controls the localization of the problem. The degree of difficulty varies from place to place. Blanket elimination and blanket similarity of approach do not seem to fit the case. However, in each area where the situation has become acute, in regard to either domestic or industrial waste, the time has arrived for a definite position on the part of the people as to the balancing of convenience in the use of the stream.

---

[25] Prof. of San. Eng., Johns Hopkins Univ., Baltimore, Md.

Many frank critics of the rush toward stream-pollution abatement are emphasizing the fact that correction, particularly in reference to industry, may militate against the advantage of the region forced to clean up. The weight to be given such considerations should be determined in each case upon the merits of the facts; that the facts should be adequately balanced should certainly be borne in mind.

Law

Law enforcement as a device for the control of any difficulty is frequently the first recourse of certain groups of individuals. The popular phrase "there ought to be a law" exemplifies this faith in correction by legislative fiat. Experience discloses, however, that no greater progress in stream pollution abatement has occurred in those States where rigid legislation has been on the books for many years than where such laws are absent.

This situation has led some people to suggest that the difficulty lies in the inconsistency of individual State Acts. They argue that corrective measures are impossible in one State because similar corrective measures are not executed in another State. This leads to the further suggestion that the only corrective in law is a comprehensive and overlying Federal anti-pollution act. Aside from inherent fallacies in logic, many students of the problem believe that such Federal legislation is unconstitutional. More important is the belief that it would be unwise, not only because the mere passage of an act need not result in correcting difficulties, but because the long and time-consuming negotiations for stream correction are logical fields for local participation and autonomy.

State by State progress in stream-pollution control has been uneven, and uncorrelated with legislative pronouncements. If anything, it has been related primarily to the enthusiasm, ingenuity, and co-operative endeavor of individual State departments and of municipalities and industry.

It is the writer's opinion that the secret of successful stream-pollution control does not reside in the extension of legislative restriction.

Scientific Knowledge

A review of the record discloses that solutions to many of the problems in trade waste treatment and recovery are not yet apparent. In this particular field the solution obviously lies in a more intelligent, consistent, and continued participation of industry in the search for an answer. Inertia and ignorance on the part of industry have perhaps been responsible for more delay and less accomplishment in the control of stream pollution than any other factor. The industrial sewer has been out of sight and hence out of mind. Industry's wastes have not been one of industry's major responsibilities.

However, industry cannot continue to content itself with negative resistance to extension of legislative control; it must begin to traverse more positive paths toward the development of scientific and economical methods of industrial waste treatment. On industry rests the responsibility of evaluating its contribution to the problem, of determining its method of attack, and of demonstrating its willingness to assist in the solution of one of the important problems of national economy. American industry particularly cannot afford to be accused of being unable to solve the technical problems of waste treatment, when its accomplishments in the allied fields of technological production have been as varied, as successful, and as inspiring as they have been.

As for the treatment of domestic wastes, the state of the art is sufficiently advanced to require no similar pressure. Obviously, certain technical facts are still lacking and scientific diagnoses and procedure still need to be developed, but economical and satisfactory processes of treatment are at hand to meet the issue.

MONEY

The key to the primary question of what can be done about pollution, to the writer's mind, lies in money. How can stream-pollution correction best be paid for? "Depression thinking" has given even greater emphasis to the ever-present question of how to raise money for sewage disposal and treatment. Such an enterprise is seldom popular, largely because, in most instances, the sewage nuisance is remote from the average taxpayer's eyes and nose; and in the years of depression, money for such purposes has become increasingly difficult to raise. A revival of a criterion of decency in the American public conscience is a first essential, but no less important is the development of financial techniques for raising funds.

Experience since 1933 has indicated how important an impetus may be given to sewage treatment plant construction by the artificial device of Federal grants-in-aid. More than 25% of existing sewage treatment plants in the United States have been constructed since 1933. It is difficult to believe that this is the result of chance or of a simple natural process of growth, rather than the obvious result of the artificial stimulation of activities in this field by Federal funds. The principle of grants-in-aid to stimulate special types of local endeavor is of course not new; it has been applied for more than fifty years in a variety of highway, navigation, reclamation, public health, and agricultural projects.

This experience leads the writer to suggest that perhaps the most valuable stimulus for correction of stream pollution is in the grant-in-aid principle. It need not follow, of course, that the grant-in-aid from a Federal Government is a pre-requisite, although it makes for uniformity of action throughout the country. The possibility of extending the State grant-in-aid procedure to sanitary projects is an opportunity for real progress. Such a procedure, within the State, again has precedent in the fields of education, agriculture, and highways. It has the merit of continuing and preserving the important local autonomy and responsibility which concerns so many at this time.

In other words, if money is the key to stream-pollution control, a central stimulation of activity—based, of course, upon a reasonable balancing of convenience—offers one of the soundest bases for future success. Correction is cheap, as such expenditures go, but the incentive has been missing.

SUMMARY

This brief discussion leads to the following answers, positive and negative, to the question of "What can be done about stream pollution?"

(1) Standardization of State laws on the subject is desirable. Too much faith in the efficacy of the law, however, is not warranted by past experience,

or the temperament of the American people. If the people are not ready, the law fails.

(2) Industry must show a greater interest in the problem of industrial waste. It must demonstrate that it is attempting to find economical solutions to these problems.

(3) State or Federal financial stimulation of sewage treatment plant construction offers a useful device for increasing the rate of installation of stream-pollution corrective equipment. It is perhaps the most helpful direction in which progress is to be made. Its political implications and its dangers must be carefully scrutinized. With proper control, however, it has demonstrated its possibilities of success.

(4) The permanent control of the situation lies in the co-operative effort of the public official, the private investor, and the man in the street. Intelligent appraisal of the problem and of the benefits to be derived from its correction should be the guide. Hysteria and undue charges in this field, as in any other, are not likely to produce permanent answers to the problem.

DISCUSSION

D. E. Davis,[26] M. Am. Soc. C. E. (by letter).—The paper by Mr. Streeter supplies for the first time a quantitative measure of the effect of acid in the reduction of bacteria in the Upper Ohio River. That the "step-down" method utilized in reaching these conclusions possesses validity is demonstrated by the close correspondence between the calculated and the observed results. That acid reduces the pollution load appreciably is indicated by the *B. coli* count at Wheeling, W. Va., which under winter conditions is 25% and under summer conditions is less than 1% of what might be expected under normal alkaline conditions.

The 1932 studies of the Pennsylvania State Health Department, under the immediate direction of Mr. L. S. Morgan, District Engineer, indicated that at Sewickley, twelve miles below Pittsburgh, the results are even more striking, since under the summer low-flow conditions in 1932, the *B. coli* index was 165 (compared to 3 760 for Wheeling), or only a fractional part of 1% of the anticipated results under "normal" conditions. They also indicated that for corresponding river flows, the oxygen content of the river in 1932 was better than for the 1914–15 period, in spite of a considerable increase in the population in the District. This unexpected result may have been due to the substantial cessation in the intervening period of the activities of the brewery and distillery industries, whose wastes make a heavy oxygen demand on the rivers. The increase in acid, experienced since 1914, had very decidedly reduced the bacterial load, and on these two counts the river water was better during low-flow periods than in earlier years.

Although it is known that acid reduces the "bug counts," it is not clear how this result is achieved. Whether the acid actually kills most of the *B. coli*, as chlorine does, or whether it merely makes them "play dead" like a "possum," only to come to life under alkaline conditions below, is a matter of conjecture as yet. No complete differentiation has been made as between the different strains of *coli* to lead to a certain conclusion as to whether acid may have a selective action, killing off permanently the pathogenic types and letting some other more resistant organisms continue their life cycles. An alternative possibility is that during periods of low-flow, coagulation and sedimentation effect the prompt deposition of bacteria on the river bottom, where they may lie dormant until the first freshet scours them out to increase enormously the load on down-stream filtration plants.

The rôle of plankton in the self-purification of streams under acid conditions is not yet completely understood, nor is there a definite correlation between plankton and bacteria, which might serve as a guide to the degree of purification which has taken place. It was shown in the 1914–15 studies that there was an abundance of plant life in the acid Monongahela, but that it was confined to a relatively small number of species. It was suggested that these types might have the ability of ingesting organic matter without the interposition of bacteria. It is entirely possible that some of these forms of life find optimum environments under acid conditions.

---

[26] Engr. (The Chester Engrs.), Pittsburgh, Pa.

It has been noted that certain forms of grasses or "sea weeds" have begun to flourish increasingly in the Allegheny River as it has become more acid. The pools immediately below Pittsburgh (with pH usually on the acid side) are literally alive with this type of growth which flourishes on the rich river mud. The studies of the U. S. Public Health Service have shown that these plants, in generating chlorophyll by photosynthesis, give off large quantities of oxygen during daylight hours, thus measurably abetting reaeration at the surface of the water. They also exert a mechanical effect in intercepting and holding floating material, later to deposit it on the river bottom, as mud into which the plant extends its roots.

It is possible that this luxuriant growth and other plankton forms may directly break down complex organic material into simpler and more stable forms even without the aid of bacteria. In other words, under these acid conditions the absence of large numbers of the bacteria that are usually found below heavy sources of pollution may not mean that the processes of self-purification are largely postponed until more alkaline conditions obtain. The work may be taken over in large part by the river plankton.

These observations suggest the value and importance of further fundamental studies relating to the effect of acid on purification processes. They are not merely academic questions. Acid admittedly takes an economic toll in its attack on exposed steel and concrete structures, and in water treatment, but the U. S. Public Health Service has raised the question as to whether its beneficial effects on sewage may not outweigh these harmful results. A mine-sealing program is being pushed which may greatly reduce the quantity of acid entering the streams. Should this be completely successful, river conditions might become intolerable and secondary sewage treatment, at a greatly increased cost, might become necessary in some communities. Furthermore, if acid acts as a germicide, this function should not be ignored, since it contributes to the greater safety of those using the river for recreational purposes.

These questions are susceptible of fairly definite evaluation and policy determination. The time is ripe for their early consideration so that money may not be expended wastefully. To quote the author, they "fall more especially in the field of research, which in the long run must keep pace with that of the sanitary survey, as the two are virtually inseparable in meeting engineering problems of stream-pollution control."

L. S. MORGAN,[27] ESQ. (by letter).—The Pennsylvania Department of Health during the period from September, 1932, to February, 1933, conducted a sanitary survey of the Ohio River in co-operation with the Health Departments of down-stream States and the United States Public Health Service. The survey extended over the stretch of the Ohio River from its source at Pittsburgh to the Pennsylvania-Ohio State line, a distance of approximately 44 miles. Sampling stations were located at distances of three, twelve, twenty-five, and forty-four miles below the source at Pittsburgh and at distances of six and thirteen miles, and of one mile, above the mouths of the Monongahela, Allegheny, and Beaver Rivers, respectively, which are the main tributaries of the Ohio River.

---

[27] Dist. Engr., Penna. Dept. of Health, Greensburg, Pa.

The main reason for conducting the survey was to determine the character and quality of the Ohio River water at and below the Metropolitan Pittsburgh District as a result of the discharge of untreated sewage in this metropolitan area.

The regimen of the Ohio River and its two principal tributaries, the Monongahela and Allegheny Rivers, is controlled by a series of navigation dams. These dams create large pools into which the sewage from a population of approximately 1 200 000 is discharged untreated in the Metropolitan Pittsburgh District from eighty-five separate municipalities, including the City of Pittsburgh proper.

The Monongahela and Allegheny Rivers drain large areas located in the bituminous coal fields of Southwestern Pennsylvania and West Virginia. The discharge of mine drainage from bituminous mines, together with the discharge of acid wastes from metallurgical plants, renders the water of the Monongahela River at its mouth acid practically at all times and the Allegheny River at its mouth acid especially during low-flow periods. These acids include free sulfuric acid, together with the sulfates of alumina and iron. The Ohio River, therefore, during low-flow periods contains varying quantities of the mineral acid and acid salts, the degree of acidity being dependent on the rates of flow and degrees of acidity of the two principal tributaries.

During periods of low flow and accompanying low velocity, the navigation pools in the Metropolitan Pittsburgh Area act as sedimentation basins in which are deposited settleable material contributed by the sewage and industrial waste discharges. Sedimentation is materially aided through the coagulation and precipitation of acid salts during periods of low flow. The passage of water at low velocities through the navigation pools and over navigation dams permits a high degree of surface aeration. Thus, during low-flow periods, these combined circumstances provide a method of sewage disposal at least roughly comparable to sedimentation.

However, because of the acid character of the river water, bacterial activity in the deposited sludge is inhibited and, as a result, the settled material does not undergo bacterial decomposition but remains for varying periods of time in what might be termed a "pickled" or "cold storage" condition until scoured out by sudden and rapid increases in stream discharge.

At such times, as velocities increase, the accumulated material is washed down stream in concentrated form and the sudden changes in the character of river water are reported as causing an undue burden on down-stream waterworks deriving their sources of supply from the Ohio River.

During the survey, determinations of the varying sanitary quality of the Ohio River water were obtained and correlated with varying rates of discharge (see Table 6). The station selected for securing such data was twelve miles below the point at Pittsburgh and below the points of discharge of practically all untreated sewage from the Metropolitan Area.

The dilution factors shown in Table 6 for the lower flows are lower than those generally recognized as necessary under ordinary circumstances to prevent nuisance conditions. In this case, the critical discharge to prevent nuisance conditions would be approximately 5 000 cu ft per sec, based on the contributing sewered population alone and disregarding entirely the equivalent population load of industrial waste pollution which, in the Pittsburgh area, would probably equal or exceed the sewered population. Nevertheless, despite the low dilution factors, general nuisance conditions do not exist in the river.

TABLE 6.—Sanitary Quality of Ohio River Water Below Pittsburgh, for Various Rates of Flow

(Data from Survey of 1932–1933)

Average daily discharge, in cubic feet per second	Dilution factors, in cubic feet per second per 1 000 population	Average dissolved oxygen, in parts per million	Average 5-day bio-chemical oxygen demand in parts per million	*Coli-Aerogenes* Index per 100 Cubic Centimeters	
				Average	Maximum
1 500	1.2	6	0.2	160	700
2 900	2.4	7	0.5	160	670
7 200	6.0	11	2.5	290	3 400
19 400	16.2	12	2.6	4 300	36 700
44 000	36.6	13	3.5	5 300	37 000

The relatively high dissolved oxygen content at the various rates of discharge indicates that the oxygen resources of the stream are not being depleted to the point where general nuisance conditions would result. These high results also indicate that the dissolved oxygen available is not being utilized for the oxidation of organic material through bacterial activity.

The five-day B.O.D. is much lower during low-flow periods than would ordinarily be anticipated, but is more nearly normal during the higher flow. Based on the contributing sewered population the anticipated B.O.D. would probably vary from a maximum of approximately 37 ppm at the low flows to a minimum of approximately 1.5 ppm at the high flows, with the organic pollutional load uniformly distributed over the entire flow range. Assuming a reduction in organic material of 35%, equivalent to the removal obtained through sedimentation during low-flow periods, the resulting anticipated oxygen demand would still greatly exceed the observed values. It is, therefore, believed that the concentration of acid during low-flow periods renders the B.O.D. determination unsatisfactory as a yardstick for measuring the true pollutional load of organic material and that some revision in the standard procedure is necessary to obtain a true picture under such conditions.

The *coli-aerogenes* index shows clearly the inhibiting effect of the acid condition in the river at low stages. With increased discharge, the index shows a decided increase probably more nearly representing normal conditions. In the absence of acid wastes and under similar pollutional loads much higher indices would be anticipated.

These results indicate a fairly stable condition in the Ohio River below Pittsburgh during periods of low-stream flow due to the presence of acid wastes inhibiting normal biological and chemical processes of purification and preventing general nuisance conditions. With increasing stream flow, however, resulting in more normal conditions through dilution of the acid wastes, the results more nearly represent the anticipated conditions resulting from the discharge of untreated sewage from such a large population.

C. A. HOLMQUIST,[28] ESQ. (by letter).—In reviewing Mr. Stevenson's paper the New York State Department of Health finds itself in general agreement with the treatment which he has given the subject. During the July, 1935, floods, conditions in New York State were comparable with those suffered in Pennsylvania and other States during March, 1936, and the Health Department's activities and policies with respect to protection of the public health at that time closely paralleled those undertaken and followed in Pennsylvania. During the 1936 flood, conditions were less severe in New York State. However, these two flood experiences have enabled the New York State Department of Health to formulate a somewhat definite plan of action and policy to be followed in future floods.

There is one point mentioned in Mr. Stevenson's paper however, with which the writer is not in complete agreement. This is in reference to the issuance of general and unqualified "boil-water" warnings in times of such catastrophes. There are, of course, certain differences in the organization of public health work in the two States that might make the policy followed by Mr. Stevenson perfectly proper for his State and improper for New York. In New York State there are many competent local health officers and water-works officials upon whom the Health Department can always rely—who would be the first to advise the Department if anything were wrong—and upon whom it would place the responsibility for deciding whether or not a "boil-water" order should be issued. During both the 1935 and 1936 floods the Department issued promptly general "boil-water" warnings, and it is believed that such action is advisable. However, these warnings were qualified in such a way that they left to the local health officer final decision in the matter. People were advised generally to be guided by the suggestions of their local health officers and water-works officials, but, in case there was any doubt as to the safety of the supply, to boil their water or treat it with chlorine compounds of various kinds as a precautionary measure, until the exact condition of the supply could be ascertained. Had these general warnings been issued without some qualifications, the people of Albany, for example, would have had to boil their water—which would have been unfortunate in view of the known safety of that supply. Even with the qualified "boil-water" warnings there were several instances when health officers issued local warnings which were unnecessary. However, in such cases, the local health officers were uncertain as to the conditions, and there is no criticism under the conditions prevailing of "erring on the side of safety."

Mr. Stevenson has stated that the primary responsibility for protecting the public health in time of floods should rest upon local authorities. This should be emphasized in the strongest terms possible. State Health Departments and other units of State Government can furnish valuable guidance and assistance during emergencies, but local health officers, local water-works officials, and other local officials have the real opportunity of reducing to the irreducible minimum the public health hazards which invariably arise during such periods. The protection to the public health at such times is likely to be very much in proportion to the ability of the local officials to meet the problems promptly and properly.

---

[28] Director, Div. of Sanitation, New York State Dept. of Health, Albany, N. Y.

Therefore, in any planning which should be done in advance to meet the public health needs of possible future catastrophes, training of local health officers and water-works operators or superintendents should be the central objective. A State Health Department should strive to provide continuously, through water-works schools, frequent inspections of supplies, etc., for the general education and training of local officials. It should seek to bring all of them to a high level of competence so that when floods occur they will know what to do, how to do it, and have the essential equipment at hand for their work.

In stressing the importance of the training of local health officers and water-works operators, the writer is not unmindful of the great need for physical improvements in supply systems that will lessen the danger of failure or contamination during floods. Water-works officials should throw overboard the philosophy of "The Arkansas Traveller," who "wouldn't repair the leak in the roof when it was raining, because then he couldn't work, or when it was not raining, because then it didn't leak." The time to make improvements to lessen the hazards to public water supplies occasioned by floods is before the floods occur. State health officials frequently come to the end of their rope in appealing and preaching to the governing boards of municipalities for favorable action on important matters. The chance of success is always enhanced considerably when there exists in the local community a health officer or local water-works man who is thoroughly trained and imbued with the proper sense of public health values. Therefore, the proper training of local officials is the important objective. Carried to the proper end effort expended in this direction will not only equip the local health officer or water-works official to respond with the maximum efficiency during any emergency but will also help to bring about many of the important improvements in public water supplies which will lessen the dangers during emergencies and which to some extent may at present be opposed by insufficiently impressed local officials.

ROBERT SPURR WESTON,[29] M. AM. SOC. C. E. (by letter).—In Mr. Stevenson's thorough review of the sanitary problems incidental to floods, he has set down little to criticize and much to commend. His administrative experience as public health engineer for a large and varied State permits him to speak with authority. The statement of a private practitioner must necessarily be limited in comparison.

More people comprehend the practical engineering problems in the construction of flood reservoirs than the social problems involved. Imagine, for example, as might be the case on more than one river system, a series of upland valleys which are excellent sites for flood control reservoirs but which are occupied by expensive summer residences, country clubs, and the hamlets which they support. Down below are mills and cities, damageable by floods and supporting a large population; but try to apply to the situation the methods so successful on the Miami River, and then watch the summer residents rush to the State Houses and to their powerful political friends. They would say "dike or otherwise protect," or, "move low-class dwellings and shops away but leave us our homes and our æsthetic enjoyment." Again, there is the resistance of the taxpayer to benefits which accrue to riparian dwellers but not directly to him. These and other difficulties are often controlling.

---

[29] Cons. Engr. (Weston & Sampson), Boston, Mass.

It is reported that when Germany decided to war against France in 1870, von Moltke took a stack of telegrams from his desk and, sending them, mobilized the Prussian Army for victory. An analogous preparation is required for the successful control of the public health during floods, as Mr. Stevenson has shown.

As he states, the safeguarding of water supplies is of greatest importance. It is far better, however, to have water-works flood-proof than to depend upon emergency measures when the floods arrive.

In Massachusetts, when the laboratory of the Department of Public Health, at Lawrence, was flooded into temporary desuetude, a number of private laboratories were called upon to assist. Viewing their results, it was rather surprising that even when the flood was at its height almost none of the tube well supplies in the flooded valleys went bad. On one day, out of eighteen samples collected, mostly from ground-waters in the flooded Charles River Valley, only one was polluted and that one only slightly, showing the value of good construction and the protection given by impervious layers in the soil.

It must be realized, however, that Massachusetts is particularly fortunate in having only one water supply from a polluted river. The problems which confront the cities whose sites dot the courses of rivers in the great valleys, where rivers are necessarily both sources of water and places of final disposal of sewage and waste, are happily absent. In Massachusetts, too, 97% of the population has access to public water supplies, and 87% is tributary to sewerage systems.

During the flood in Massachusetts, the inspiring aspect was the efficiency of the Department of Public Health; the depressing aspect was the lack of comprehension and organization shown by some of the municipal departments. Co-operation among towns under State leadership was excellent. At Lawrence, for example, hose connections were made to the hydrants of three neighboring towns and the supply was thus maintained.

Flood control is important, but safe water supplies and sewage disposal are more important. Consequently, no scheme of control should be planned without regard to the public health factors, and the judgment of the health authorities should be taken into account in any decision regarding works for flood control.

The U. S. Supreme Court, through the late Associate Justice Oliver W. Holmes, lucidly stated that "a river is not an ordinary amenity but a treasure." If so, all the treasurers, including the hydrologist and the public health engineer, should control the assets and liabilities. Furthermore, it seems best to have these treasurers appointed by the States and do the business which is necessarily inter-state by using compacts and agreements, rather than by submitting to

Federal regulation or direction. Federal data and advice, however, should be welcomed and their costs cheerfully borne.

Karl Imhoff,[30] M. Am. Soc. C. E. (by letter).—An impounding reservoir or a sewage lagoon is a natural purifying arrangement for sewage or polluted streams.[31] In Germany, many plants of this type, both large and small, are operating satisfactorily. Purification takes place according to the same rules as in the self-purification of streams. It is possible to calculate the oxygen demand so that the amount of oxygen used can be equalized with re-aeration. In making such a calculation, various factors must be taken into account:

(1) The consumption and the absorption of oxygen depend on the detention period and on the temperature. Absorption is governed, in addition, by the rate of oxygen demand.[32] Complete biological purification may be assumed to take place in 20 days detention at 20° C.

(2) Oxygen absorption is also proportional to the surface area of the pond. The greater the surface and the less the depth of the pond, the greater will be the oxygen absorption for any given volume and detention period.

(3) For all depths of more than approximately 2 ft, the depletion of oxygen and the speed of decomposition are constant. For depths of less than 2 ft, the speed of decomposition increases rapidly with decreasing depth, probably because the plant and animal life on a lighted bottom has a stronger effect. In very shallow ponds the biologic purification is completed in a few days.

(4) Sunshine generates more oxygen from green water plants than the water will absorb from the surface.

(5) A completely still water surface takes little oxygen from the air. Every wave, whether from wind or boat, increases the oxygen absorption greatly.

(6) Sludge in sewage lagoons should be eliminated as much as possible by the use of settling tanks. Some bottom sludge will accumulate anyhow, because settling occurs in quiescent lagoons, even with pre-settled sewage. The accumulation of bottom sludge is continuous throughout the year, and is due to putrefactive bacteria which, in turn, use oxygen. The greatest demand on oxygen is during the warm season, just when the flow is diluted the least. The oxygen demand of the accumulated bottom sludge is at such times generally much higher than that of the dissolved organic matter which flows through uniformly. (The three sludge lagoons in the Ruhr Valley, Germany, have the advantage of being scoured by flood waters almost every spring, and even during the summer, they are not heavily loaded with sludge. If such natural washing does not occur, it may be advantageous to dredge the bottom.)

Henry D. Johnson, Jr.,[33] Esq. (by letter).—The subject of planning for pollution control at Pittsburgh has been covered in a most able manner by

---

[30] Cons. Engr., Essen, Germany.

[31] "Impounding Reservoirs as a Substitute for Biological Sewage Treatment Works in the Ruhr District," by Karl Imhoff, *Sewage Works Journal*, January, 1931.

[32] "Measures of Natural Oxidation in Polluted Streams," by H. W. Streeter, M. Am. Soc. C. E., *Sewage Works Journal*, March and May, 1935.

[33] Former Chf. Engr., Dept. of Public Works, Pittsburgh, Pa.

Mr. Davis. The writer knows of no one in that city who is more familiar with this subject than he. It seems almost obvious that Pittsburgh engineers and municipal authorities must start entertaining plans for the treatment of the sewage and industrial wastes, but whether or not the time has yet arrived for building an extensive and expensive sewage treatment system is difficult to say.

The writer is personally interested in pollution control at Pittsburgh because of his interest in the possible recreational facilities afforded by the near-by streams. Much of the enjoyment of water sports is taken away by the sewage and industrial waste pollution which exists throughout the stretches of the three rivers within Allegheny County. When one is able to cruise up stream beyond the locations of large cities or boroughs, or above large industries and above those streams which drain mines, one finds the rivers in almost their primitive state. They are beautiful and attractive beyond words. It is not to be expected that any feasible plan of sewage treatment and industrial waste control will restore the rivers to their original purity, but there is no question that the pollution could be reduced sufficiently to make safe the use of the rivers for sports.

Mr. Davis' conclusion that primary treatment by sedimentation will be the only form of treatment required for some time to come, is in general correct, although certain communities that discharge their wastes into small streams will unquestionably have to consider complete sewage treatment in the immediate future.

Recent studies on the costs of the proposed plants indicate that it would be possible to afford very definite relief at a more or less nominal figure. Earlier reports and studies have been based on the premise that the effluent from treatment plants should be bacteriologically pure. However, a comparison of the costs of establishing water purification plants for down-stream communities, with the additional cost of sewage treatment plants which would provide a pure effluent, shows that, at present, it would be more economical to provide adequate water purification plants and only primary treatment for Pittsburgh and its environs. The primary treatment of sewage would unquestionably benefit those sections of the community which border the streams, because of the consequent elimination of sludge beds with their attendant foul odors and unsanitary conditions.

As Mr. Davis points out, the topography of the Pittsburgh District is such that consideration cannot be given to sewage treatment for the municipality of Pittsburgh alone; all or most of the cities, boroughs, and townships of Allegheny County must be considered. There are 116 municipalities using the three canalized rivers for disposal, and it would be futile for any one of these municipalities to attempt a solution of the problem without the co-operation of all the others.

To avoid petty politics and party dickering the only possible way to secure action is by legislative fiat. The time is now ripe for civic bodies and various leagues of voters to support legislation leading to the desired end.

The writer is not prepared to state that the plan for sewage treatment developed by the City of Pittsburgh is the best possible one. In any event, however, it can be made the basis of a final plan, and, as such, it should be endorsed by civic bodies for the purpose of obtaining the support of the citizens. Then, when the appropriate time comes, some plan (perhaps the present one) should be endorsed by the Legislature and each municipality should be required to adhere thereto. In lieu of the foregoing it might be proper for the Legislature to establish a Metropolitan District Plan, combining the municipal bodies of Allegheny County into a Sanitary District similar to that in Chicago, and empowering the officials of the district to raise funds to carry out and supervise the construction, maintenance, and operation of treatment plants, intercepting sewers, and, eventually, of disposal plants.

Charles M. Reppert,[34] M. Am. Soc. C. E. (by letter).—The paper by Mr. Davis is a most interesting and timely discussion of one of the most important problems confronting Pittsburgh and its metropolitan area. There are some very unusual features involved, which must be fully taken into account. Inter-relationships with the acid mine drainage and proposed storage reservoirs are involved and there are many difficulties due to the nature of the topography. It is clear, as Mr. Davis states, that the situation can be met only by co-operative action of the many municipalities involved in adopting, financing, and carrying out a plan. The questions involved are: (1) The present necessity for reducing the sanitary load on the Ohio River in the interest of down-river water supplies, or for the prevention of general nuisance in the stream below Pittsburgh; (2) the need to prevent local nuisance along the shores of the rivers, particularly along the margin of the down-town business district; (3) the effect of reducing the acidity of the rivers by mine sealing; and (4) the effect of the construction of the system of proposed storage reservoirs for flood prevention and their utilization for increasing the dry-weather flow.

With regard to general nuisance at low stages in the Ohio River, below Pittsburgh, it can be stated that although a critical condition has been approached it has not been reached, probably because the increased sanitary load has been offset by the increased acid content of the rivers. It is evident that the effectiveness of mine sealing in reducing the discharge of acid mine water becomes one of extreme importance. It must be realized, however, that the acidity problem is one of control rather than elimination. Although the Monongahela River has been acid for many years, the Allegheny was alkaline until 1923; since that date it has shown a marked upward trend in acid content and in the frequency and duration of acid periods. As a matter of water conservation, the mine-sealing projects which have been carried out have been fully warranted in the public interest. On the other hand, a material reduction in the acid content during low-water periods would undoubtedly lead to a most aggravated condition of gross nuisance in the Ohio River below Pittsburgh. There is, however, a limit to the acid-reduction that can be secured by mine sealing, and it has not been demonstrated that the reduction will reach a degree that will affect the sewage disposal problem to a great extent. However, such possibility should be thoroughly investigated.

The sealing of the mines will be well worth while if the upward trend of concentration can be stopped and the extreme intensities prevented. It is evident that this particular question should receive further study, as it has great effect upon what provision should now be made for secondary treatment. If mine-sealing operations can be continued so as fully to cover the tributary coal areas, and if their effectiveness is such as to assure a very material reduction in acid content of the river water, then provision should undoubtedly be made for the early installation of secondary treatment works.

---

[34] Civ. Engr., Pittsburgh, Pa.

The effect of sewage discharge from the Pittsburgh area on down-river water supplies is of the greatest importance in determining the immediate necessity for sewage treatment at Pittsburgh. At the present time it appears that this effect is of concern during rising, rather than at low, river stages, and that critical conditions obtain or are approached during rises in the Ohio River, following prolonged low-water stages, at which times the sewage sludge deposited in the beds of the rivers at Pittsburgh and held in a state of retarded decomposition is scoured out and carried down stream. It is evident that, if the pollution contributed by Pittsburgh at the present time is materially affecting the difficulty and safety of purifying down-stream water supplies, any appreciable increase in the sewage load or the occurrence of abnormally long dry-weather periods would greatly aggravate the situation. Further data, however, should be made available as to the proportion of the pollution load contributed by Pittsburgh compared with that contributed from other and local sources.

What will be the effect of the construction of the system of proposed storage reservoirs now receiving the attention of local, State, and Federal authorities? Engineers of the Pittsburgh Flood Commission have estimated that the utilization of storage during dry-weather periods will increase the dry-weather flow in the Ohio River, at Pittsburgh, about 250 per cent. If this condition is brought about, then the necessity for secondary sewage treatment will be deferred for some years, and the number of primary treatment plants needed at present might be reduced. This would enable the adoption of a construction program covering a period of years.

The existence of local nuisance along the river shores at Pittsburgh constitutes one of the strongest local arguments for undertaking primary sewage treatment without delay. Such nuisance has increased in recent years, and has become particularly offensive on the margins of the down-town business district. Public decency and civic pride demand its abatement; if it is allowed to continue and to increase, depreciation of property values will result.

The writer is fully in accord with the proposed general plan described by Mr. Davis for the installation of a number of treatment plants located with due regard to economy and topography. Primary treatment will unquestionably suffice for a number of years, but it will be necessary to locate and design the treatment works in such manner that they will fit into the future installation of secondary plants. Likewise, the areas of the sites selected should be adequate for such future needs.

The first steps have been taken in solving the problem of pollution control at Pittsburgh. The Metropolitan Main Drainage Survey Project has made available necessary sanitary data and general plans and estimates. The definition of sanitary policy for this District has been made possible. Further studies should now be made of sewage characteristics and flow, acidity, and the effect of storage reservoir construction. The selection, availability, and cost of plant sites should be investigated in detail, with due reference to the cost of collection, which is an important matter because of topography and shore conditions. Finally, a decision should be made as to the program of construction—which, for financial reasons, should preferably be spread over a term of years—and the preparation of construction plans for the works to be first undertaken should be started so as to develop fully and settle all questions as to location, economy, and cost. These steps should be taken by the local authorities who will be responsible for the construction and operation costs of the works, in order that public funds be expended only to the extent that conditions require and with proper relation to other needs.

EDWIN K. MORSE,[35] M. AM. SOC. C. E. (by letter).—The paper by Mr. Ryder is unusually presented and very fair, and the writer has only one comment to make on it. Most of the head-waters of the Pymatuning are swamp lands and very flat country, which, of course, make the run-off of that river much more uniform than that of any other river west of the Allegheny Mountains in the Commonwealth of Pennsylvania. To the extent that this condition affects the results of the reservoir operation, the paper might be misleading to an engineer not acquainted with the location.

In several public talks on the Pymatuning, the writer has emphasized the necessity of building a reservoir on the Cussawago River, in a water-shed six miles from the Pymatuning Reservoir, and connecting it by a tunnel and open ditch to the latter. Then, when water is required from the Pymatuning Reservoir in the low-water period the gates of the Cussawago could be opened and the water of that reservoir be permitted to flow through the Pymatuning, thereby maintaining the lake level in the latter during that part of the season when it would be a great recreation center for approximately 3 000 000 people within a radius of seventy-five miles.

The dry season in this vicinity generally takes place from about the first of July to the first of November, but the schools open early in September, and the resort would be materially vacated by the first of October.

JAMES H. LEVAN,[36] ASSOC. M. AM. SOC. C. E. (by letter).—General methods and laboratory tests applicable to a pollution survey of any stream are given in this paper, and Mr. Streeter has mentioned the fact that additional tests will depend upon the circumstances of the particular survey being made. It is very necessary that consideration be given to the uses that are made of the stream and to the presence of undesirable substances in the water, particularly to the substances originating in industrial wastes. A survey being made must take into account all pollution factors of the river under consideration. Too often only dissolved oxygen (D.O.) and bio-chemical oxygen demand (B.O.D.) tests are considered. The importance of the bacteriological and biological tests is not always realized. The former give the most sensitive indices of significant changes in the pollution of a river. The latter tests will "go hand in hand" with the other tests and will aid in solving questions that arise when unusual chemical and bacteriological results are obtained.

---

[35] Cons. Engr., Pittsburgh, Pa.

[36] Passed Asst. San. Engr., U. S. Public Health Service; Officer in Chg., Aedes Aegypti Control Unit, U. S. Quarantine Station, Miami Beach, Fla.

The U. S. Public Health Service is making a study of the Scioto River, from Columbus, Ohio, to its point of discharge into the Ohio River at Portsmouth, Ohio. The purpose of this survey is to observe the changes that occur in a polluted stream as the major sources of pollution are controlled by the construction of waste treatment plants. Already the City of Chillicothe, Ohio, has placed a new sewage treatment plant in operation. The City of Columbus closed its overloaded plant in 1937 and has turned all its sewage into the primary settling tanks of its large new plant, pending the placing of this activated sludge treatment plant in operation. The City of Circleville, Ohio, midway between Columbus and Chillicothe, is about to construct a plant. At this point wastes from a strawboard paper mill and several canneries enter the Scioto River. There are two paper mills at Chillicothe with wastes that discharge untreated into Paint Creek, one of the main tributaries of the Scioto River.

For this river study, it was necessary to select sampling points that would give information above and below the major sources of pollution, and above and below the river's main tributaries. Fortunately, highway and railroad bridges are situated at points where sampling stations should be established to obtain this information. As the survey progressed the results obtained showed the section where most rapid self-purification was taking place, and, consequently, where there should be the most frequent and intensive sampling. Likewise, stretches were revealed, where the river was becoming stabilized and where sampling need not be as frequent. As there is a limit to the laboratory work that can be performed by the personnel of a field laboratory, it is necessary that the officer in charge of it observe carefully to see where efforts should be concentrated and where unnecessary sampling may be discontinued. He must be on the alert for all changes that occur in the river and alter the work of the laboratory accordingly.

The following determinations are made on river samples at the Scioto River Investigation Laboratory, at Chillicothe: Temperature (at the time each sample is collected); suspended solids; methyl orange alkalinity; pH; dissolved oxygen (D.O.); 5-day bio-chemical oxygen demand (B.O.D.); bacteria growing on agar at 37°C, in 24 hr; and the most probable numbers (M.P.N.) of sewage bacteria (coliform group). In warm weather the dissolved oxygen and the bacteriological samples are transported by automobile to the laboratory in an iced container. Although the dissolved oxygen determination should be made as soon as possible after the sample is collected, the method used in this survey permits it to be done in the laboratory by a sanitary chemist instead of by a sample collector in the field. In addition, on one sample daily, B.O.D. determinations are made on identical samples with incubation periods of 3, 5, 7, 10, 12, 15, 20, and 25 days to check the course of the oxidation curve through the primary (carbonaceous) and secondary (nitrification) phases. Furthermore, one sample daily receives bacteriological examination through the completed test; the others receive the partly confirmed test using brilliant green bile (2%) broth. To save work in the field laboratory, composite samples preserved with concentrated sulfuric acid are sent monthly to the Stream Pollution Investigations' Laboratory, at Cincinnati, for nitrite and nitrate determinations. At times, these determinations are also made at the field laboratory to check up on advanced nitrification.

As part of the study of the Scioto River, a biologist makes weekly examinations of river samples. One week he examines freshly collected samples and the next week formaldehyde-preserved samples are sent to him at his Cincinnati headquarters. Mud samples are sent monthly to Cincinnati for examination. The biological forms play an essential part in the natural purification of a stream, and only by regular biological examinations can the changes in kind and relative numbers be recorded during and following a stream sanitation program. The biological examinations should never be slighted or minimized.

Unless the officer in charge has good reasons for doing so, all chemical, bacteriological, and biological examinations made on water samples should conform with the regularly accepted standard methods so that the results obtained will be comparable.

Present-day methods of automobile transportation permit samples to be transported to the laboratory with dispatch. It is more difficult to collect the samples at the correct stream points so that a representative sample will be secured each time the sampling can is lowered into the river. If bridges are not convenient, boats will be necessary unless the stream is so shallow that it can be waded. (The U. S. Public Health Service has a standard sample collecting can.[37]) Portable laboratories in automobile trailers can be used for the study of industrial wastes and untreated sewages when a large river system is surveyed.

When the study of stream pollution is undertaken nationally surveys will be made on many streams for which hydrometric data will not be available. Such situations will require the establishment of gaging stations on the main streams studied and on all their important tributaries, the regular collection of gage height records, and discharge measurements to prepare rating curves. Where such data cannot be obtained float measurements may have to be substituted, or some other method will have to be devised to obtain these data. It is necessary to know the different quantities of dilution water that enter a river system and the mean velocities and times of flow at different stages.

JOHN C. H. LEE,[38] M. AM. SOC. C. E. (by letter).—It is axiomatic that, with public opinion in support of a law, much can be accomplished; but without such support, results may be incommensurate with effort. For years, and until recently, the public's attitude toward stream-pollution prohibition has been apathetic, and even antagonistic; but, of late, the Army Engineer has been able to quote Section 13 of the 1899 River and Harbor Act, and the 1924 Oil Pollution Act, effectively.

---

[37] *Public Health Bulletin No. 171;* also, Supplement No. 90, Public Health Repts., U. S. Public Health Service, Washington, D. C.

[38] Col., Corps of Engrs., U. S. Army; Div. Engr., North Pacific Div., Portland, Ore.

The Army Engineers have approached the problem along the Lower Delaware River enlisting the co-operation of industry, seeking a solution to each plant's problem that will be the least costly—if indeed an actual profit cannot be achieved from the by-products. The Army Engineers' inspectors receive welcome entrée to all plants, because the executives appreciate this attitude.

Publicity is probably as great a threat as prosecution. Industries spending thousands of dollars for public good-will are quick to realize the impending loss of that good-will, if they are posted as underminers of public health. It is not difficult to get plant executives to write their own "sentences"—what they will do to abate or remove pollution, and when—through co-operation rather than prosecution.

All that is required is patience and persistence and some persuasion. Army Engineers have contacted nearly two hundred industrial plants along the shores of Delaware River and Bay within the two years, 1936 and 1937. Without exception, all executives have responded—some more effectively, but all willingly. Impartial observers have expressed realization of improved conditions on the waters of the port, which are being sampled periodically.

In order to bring the municipalities into effective co-operation, the Army Engineers, with the written approval of the local authorities, have written into a new project report for the Delaware's channel—Philadelphia to the Sea—the requirement that annual maintenance dredging of 100 000 and 10 000 cu yd must be performed, respectively, by the Cities of Philadelphia and Camden, N. J., until they shall have made effective installations of primary sewage treatment works.

The plan for the culm-polluted Schuylkill River is based upon the principle of co-operation between the anthracite industry and the public agencies charged with the administration of the plan of recovery and improvement.

W. H. WISELY,[39] ASSOC. M. AM. SOC. C. E. (by letter).—One of the authors, Mr. Streeter, does well to place emphasis on the need for consideration of stream usage in the planning and interpretation of stream studies to be used as bases for pollution-control programs. It is often also advisable to give consideration to the possibility that a stream may be developed in the future for functions not utilized at present. Rock River, in Northern Illinois, for example, is potentially a fine recreational stream, within 100 miles of Chicago. At present (1938), however, it is not extensively developed for this purpose because several other streams offering vacational advantages are closer to Chicago. In consideration of present pollution abatement requirements in the Rock River Basin, the Illinois Sanitary Water Board recognized this probable future recreational development and any stream studies will be planned with this in mind.

The appropriate engineering analogy between the river system under effective pollution control and the well-designed bridge, which is used illustratively by Mr. Streeter, can be extended somewhat further. Determination of the degree of treatment required at each source of possible pollution may be likened to the design of the structural members of the bridge, under-treatment representing a weak member affecting the usefulness of the entire structure, and over-treatment representing wasteful design.

---

[39] Asst. San. Engr., State Dept. of Public Health, Div. of San. Eng., Springfield, Ill.

Where industrial pollution is of major importance in a river study, it is advisable to determine the actual operating times of the various industries during the year previous to the sampling period, in order to evaluate, properly, the residual pollution in the form of sludge deposits that may be present when sampling is begun. During sampling of the Illinois River below Peoria, Ill., and Pekin, Ill., in July and August, 1936, industrial pollution representing a combined population equivalent of 789 000 entered the river. However, several industries had operated during the winter and spring preceding the sampling period but suspended operations prior to July 1. Wastes from the latter represented an additional population equivalent of 375 000. Accordingly, it was necessary to modify computations involving the river data to allow for sludge deposits in the river during the sampling period not accountable to the pollution actually discharged during July and August.

Mr. Streeter's discussion of criteria for permissible limits of pollution of streams used for sources of water supply, commercial fishing, and industrial development is highly practical. However, there is a need for similar practical criteria to govern streams used for recreation, particularly bathing, as this usage requires much more rigid pollution control than any other.

Bacterial studies on the Upper Fox River in Illinois, in a reach used extensively for bathing and recreation, revealed that *coli-aerogenes* concentrations of 10 per 100 ml to 28 700 per 100 ml were present at some of the most popular bathing places. The program of restoration of this stream involved the requirement of complete treatment, with bathing-season effluent chlorination, at all sources of human sewage pollution so that the foregoing maximum value has been greatly reduced. Nevertheless, there may still be some question regarding the absolute protection of bathers due to combined sewer overflows and similar sources of intermittent pollution, evidencing a need for definite interpretations of bacterial analyses of the waters from this stream.

The following facts must be given consideration in the development of criteria for permissible pollution limits of streams used for bathing:

(1) A stream offering recreational advantages by virtue of its proximity to metropolitan areas and natural environment will be used for bathing almost entirely without regard for the actual existing pollution (it is very doubtful that policing of such streams as a public health measure would be practicable);

(2) It is not possible, from a practical standpoint, to maintain the water, continuously, at natural bathing places, in such condition that it will meet the usual requirements for swimming-pool waters; and,

(3) In addition to the intestinal bacteria hazard, the presence of bacteria capable of producing skin, ear, eye, and throat infections warrants consideration.

Appreciating the need for practical interpretations of bacterial concentrations in stream waters used for bathing, the Great Lakes and Upper Mississippi River Boards of Public Health Engineers have adopted by resolution, the following tabulation, indicating the "Significance of the *B. Coli* Index as a Measure of Water Pollution":[40]

Significance of Index	*B. Coli* Index, or *B. Coli* per 100 cu cm of sample
Water sample free of pollution	0
Treasury Department standard for drinking water	Not more than 1
Indicative of good water—normal for inland and Great Lakes, free of sewage pollution	10 to 100
Normal for inland streams, free of detrimental sewage pollution, might be attributed to land wash	100 to 500
Suspicious—generally indicates mild pollution in natural waters, but dangerous in proximity to fresh sewage pollution	1 000
Definite evidence of fresh sewage pollution—menace to health	10 000
Heavy sewage pollution—definitely dangerous	100 000
Normal sewage	1 000 000, or more

The foregoing classification is based on analysis of considerable data assembled by the Michigan Department of Health and the Michigan Stream Control Commission.

F. C. DUGAN,[41] M. AM. SOC. C. E. (by letter).—Stream-pollution control in the Ohio River Basin cannot be accomplished by any one State acting alone; it can result only from co-operative action by all of the fourteen States that lie partly in the Ohio River drainage area.

The *B. Coli* index of the raw water determined at the various water-works intakes along the Ohio River clearly shows that there is, at times, a very thin line of defense against outbreaks of water-borne diseases. At Ashland, Ky., it is noted that during the twelve years, 1926–1938, there were only a few months during which the average *B. Coli* index of the raw water was not greater than that which is considered as the upper limit of pollution that a water filtration plant should be required to handle. During and preceding the outbreak of gastro-enteritis, which occurred during the great drought of 1930–1931, there was not the slightest indication from the bacteriological analysis of water supplied to the inhabitants of several cities in Kentucky that the outbreaks resulted from impure water. However, it is now believed by many that the water supplies were responsible and that the causative agent was some toxin, of either chemical or bacteriological origin, which resulted from the excessive pollution by sewage and industrial wastes and which was not removed by any known method of water purification.

---

[40] Rept. on Coastline Pollution Surveys of Michigan, Michigan Stream Control Comm., June, 1933.

[41] Chf. Engr., State Board of Health, Louisville, Ky.

It is possible that the acid wastes, especially in the Pittsburgh area, have prevented local nuisances from occurring, but certainly the discharge of acid wastes is causing serious economic loss because of damaging effects on steel hulls of boats, pipe lines, concrete, and other structures, and because of the increased cost of water treatment and destruction of fish life. It is known that the bulk of these acid wastes come from abandoned coal mines, and it is essential that the mine-sealing program now (1938) in progress in several States be continued until these acid wastes are reduced to a minimum.

The canalization of the Ohio River, although it is of benefit in some respects, has intensified the pollution problem and has increased the difficulty of treating the water satisfactorily for domestic and industrial uses.

Several of the States, acting under the authority granted by a Joint Resolution passed by the Seventy-fourth Congress, have appointed commissioners who are now (1938) at work drafting a compact which will eventually lead to definite plans for pollution control in the Ohio River basin.

G. M. Ridenour,[42] Assoc. M. Am. Soc. C. E. (by letter).—So thoroughly has Mr. Streeter covered the mechanics of stream-pollution control surveys that little seemingly remains to be said in this respect. To the writer the paper clearly emphasizes five important facts: (1) That effective pollution-control results can be secured only by general control of water-shed areas rather than by local sections; (2) the extensive scope necessarily implies the establishment of large-scale technical organizations for each specific drainage area; (3) the eventual establishment of regulation by either intra-State compacts or by Federal bodies; (4) the important part that both applied and pure research must of necessity play in such stream-pollution surveys; and (5) the question as to when stream-pollution surveys become necessary.

Control by water-shed area is evidently the only logical method for securing effective, consistent, and economical solution of stream-pollution problems. Broad control of this kind seems to be without doubt the only fundamental method of attack. It is common experience to all those interested in stream pollution to observe cases of over-treatment and under-treatment of sewage and wastes in the same river basin within comparatively short distances, with attendant economical loss in both cases. Such situations have arisen not through intent, but through a combination of lack of adequate knowledge of river-purification capacities and long-range planning for the specific watershed under consideration. Fundamental knowledge of river-purification characteristics and capacities is the first requisite of intelligent planning and must be obtained through more comprehensive and embracing information than can be secured from over-burdened local sections. Treatment can be distributed economically only through a combination of knowledge of river-purification capacities and long-range planning in waste treatment. Mr. Streeter's plan of pollution-survey control meets both these requirements.

The maintenance of complete technical organizations for each specific drainage area or river basin is also an integral part of the program. Each basin will require the same routine control measures, regardless of the degree of pollution, and will likewise embrace the same basic branches of the science.

---

[42] Asst. Prof., Dept. of Water Supplies and Sewage Disposal, Rutgers Univ.; Research Engr., Dept. of Water and Sewage Research, Agri. Experiment Station, New Brunswick, N. J.

The establishment of intra-State or Federal regulatory bodies in river pollution is only a question of time. Pollution control can only be limited, temporarily, to overburdened parts of a drainage area. The ultimate direction for most successful accomplishment of the stream pollution survey control outlined by Mr. Streeter appears to lie in a national policy-making organization and local intra-State or Federal regulatory bodies applying to each specific water-shed area. The problem cannot escape a national scope without simply producing a geographical exaggeration of present local conditions.

A phase of the program which the writer feels could be more fully stressed is the important part that research should play in such stream-pollution control surveys. This research can be directed, very profitably, to increasing certain fundamental knowledge of stream-purification agencies and principles, which can be obtained only in conjunction with large-scale programs of the kind outlined.

Of greater practical significance and of vital necessity in any stream-control survey is the part that research could play in determining, more accurately, the permissible limits for pollution control. The interest in this phase of the problem has occupied second place in relation to treatment plant devices and efficiencies, with the result that wide divergencies in stream-pollution criteria now exist under different regulatory bodies. These different requirements are sufficient to make wide differences in waste-treatment requirements, under these different regulations. This applies particularly to the maximum bacterial pollution permissible for natural bathing and recreational areas, and also to minimum dissolved oxygen requirements to prevent nuisance and maintain fish life in the stream.

The pollutional indices for drinking water supplies might also be profitably subject to further scrutiny. Under growing quantities of industrial and domestic wastes, the use of the *coli* index alone for determining the suitability of a water supply may prove inadequate for determining the quality of the water. From the health standpoint increasing concentrations of both industrial and domestic wastes in the water supplies open questions as to pathological consequences of increasing quantities of organic and inorganic toxins and their limiting tolerances. This may apply particularly in cases of the more heavily industrialized and populated sections where, by continuous re-use of water, the organic and inorganic salt contents are being continuously built up in spite of present purification methods. Indices for palatableness of water have also become an important part of water standards and promise to become increasingly so in the future. Taste, odor, and physical appearance are receiving almost equal attention to bacterial qualities under present standards of most water plants, and future improvement in this non-pathological direction will depend entirely on the development of facilities, through research, to attain these ends. The source of water supply is of equal importance to the water purification process in securing better physical and sensual qualities.

Of further practical value, research may show ways and means of improving the stream as a purification unit, depending on the fullest utilization of natural local conditions of the drainage area. The receiving stream should properly be conceded as an integral unit in the waste disposal system and as occupying as important a place in the system of waste treatment as any other treatment plant unit; and as such, it deserves the same attention toward improving operation efficiency as other plant units.

The same program research can yet play a profitable part in the design and operation of waste treatment devices to secure more economical methods of treatment. This is particularly true with respect to industrial wastes, which (economically, at the present time) appear to offer the largest unsolved problem in waste treatment. There are yet many local "sore spots" within the treatment devices themselves and it seems the doubtful part of wisdom to fail to consider inefficiencies in waste treatment processes as other than an integral problem in river pollution control. The ultimate economical solution of pollution control will not be realized until the stream, on the one hand, has been made to perform its maximum work as described by accurate pollution criteria; and, on the other hand, when the methods of waste treatment are developed to their maximum efficiency.

A final question which the term, "stream pollution control," naturally suggests is, "When does a pollution control survey, as outlined, become necessary?" The first evident reason for control measures is found naturally in those cases of grossly over-polluted streams. A second, less evident, reason is found in the border line case where the conditions are approaching pollutional limits. Probably the least evident reasons are apparent in those cases of streams that are still in satisfactory condition for normal water uses, but which by potential development possibilities may be subject to large pollutional loadings in the future. From the magnitude of the problems mentioned by Mr. Streeter in the case of the Ohio River and the tremendous simultaneous economic problem involved in the case of cleaning up of grossly over-polluted streams, it would seem that the future direction of stream control surveys should be not only toward the correction of streams already grossly over-polluted, but also toward proper maintenance of river basins that are still below such conditions.

ARTHUR W. BAUM, JR.,[43] ESQ. (by letter).—The statements by Mr. Wolman that "the intensity of stream pollution is not nation-wide. It is concentrated largely in five or six of the heavy industrial States," are debatable. The relativity of intensity varies with opinion and many people of the Pacific Northwest believe that their pollution situation is also intense. For example, Oregon certainly is not an industrial State and is surely not over-populated—with slightly more than a million people in 96 000 sq miles; but it also has its pollution problems, which are of major importance.

In the industrial States the main pollution problems center around the use of the larger polluted rivers as sources for a water supply for localized population. In Oregon, the pollution problem is studied primarily for the harmful effects it has on the fishing industry (both commercial and sport) and on the public health. With ample sources of water supply available for practically every city in Oregon, it is seldom necessary to use a known polluted stream for a water supply source.

---

[43] Senior in Civ. Eng., Oregon State Coll., Corvallis, Ore.

The greatest difference in the pollution problem in one part of the United States as compared to another is represented in one's definition of "intensity." In the East, where the salmon runs have disappeared, the pollution problem is not intense to-day unless it interferes with a water supply source. The Pacific Northwest has great natural resources, especially from the viewpoint of those interested in sports and recreation, and derives a large income from this asset. More and more people are going there to enjoy the recreational facilities and the fishing offered by the streams, and as the present pollution situation is harmful to fish life and is damaging one of the region's best assets, as well as a multi-million dollar commercial industry, the pollution problem is certainly intense.

As approximately 64% of the population of Oregon resides in the Willamette River water-shed, and as the Willamette River is one of the largest tributaries of the Columbia River, it is only natural that a pollution problem is centered in this district. This area has been surveyed several times to determine the intensity of pollution present at that period when conditions are such that they should be at their worst.

The pollution situation is not a year-round problem of the same intensity, and it is only during late June, July, August, and early September of average years when there is only a precipitation of about 2 in. (and this is received in light showers), that the situation is critical. During this period the Willamette River has a minimum flow and the canneries and most other industries are running at capacity. From Salem to Portland, the oxygen content of the river gradually decreases until, in Portland Harbor, surveys show the water to have a zero oxygen content and a bacterial count at a point dangerous to the public health.[44] This "critical zone" can be considered with its two most harmful effects. It ruins a recreational area close to the major population by subjecting participants in water sports to disease and not only prevents the anadromous type of fish from passing on to the head-waters of the Willamette, but offers an insurmountable barrier to the young fish trying to reach the ocean and continue their natural cycle. Experiments have shown that a stream must have an oxygen content bordering on 3.5 ppm to sustain game fish life [45] and, if a stretch of water is present in which the dissolved oxygen content is below this point, it means suffocation to those fish trying to pass through this zone. This stretch of water in its present condition will have the similar effect on anadromous fish as cutting the bark completely off the trunk of a tree—the tree soon dies.

G. R. Scott,[46] Assoc. M. Am. Soc. C. E. (by letter).—The well-written paper by Mr. Streeter, based on detailed studies and observations of the Ohio River during the 24 yr, 1914–1938, gives a complete description of the basic data which should be collected and correlated prior to the establishment of standards of purity or requirements designed to prevent over-pollution of any river system. Instead of attempting any unnecessary restatement of the subject material in his paper, this discussion is presented solely to emphasize the need for such studies, the desirability of making them before serious conditions exist, and a general statement of the work now (1938) under way in the Tennessee Valley.

[45] "Stream Pollution in Wisconsin," Wisconsin State Board of Health, p. 249.

[46] Chf. Sanitation Div., TVA, Chattanooga, Tenn.

The natural resources of an area, whether they are the raw materials used in making finished products, or the fuel or energy necessary for the conversion, have always been the controlling factors in its development. For most industries water in some form is a necessity. Water used in the process, as steam or as the primary source of power, is usually considered a natural resource; but when used to carry away wastes, it is regarded as a fortunate convenience only—an agent that happens to be present and that is to be used for the purpose of carrying this waste material away from back doors. Many municipalities, depending as they do upon industries for financial support and population development, while at the same time providing them with their source of labor and personnel, look upon these streams with a view not much more enlightened. As a result, it is not long before such streams become little more than open sewers, having lost their valuable resources—those attributes or characteristics natural to fresh, clean streams. The water is still there and proceeds normally down its channel as before. In some cases it can be used again by others down stream after extensive and costly treatment; but in other cases it is so grossly polluted that its re-use is impracticable. This loss to the stream is accompanied by the loss of another quality, formerly considered of little value, but now being appreciated for its potentialities. This is the loss, to the area as a whole, of natural areas affording opportunity for those wholesome recreational activities which are so necessary in this energetic age for rebuilding or reconditioning the human machine so that it may be able to continue the increasing tempo of the "tread-mill." This idea, although it is persistently coming to the light, is being continually darkened by the argument that it is more important for work to be provided for the many, than that a few shall be favored by having full creels. This contention is granted; but, in general, it is quite probable that both arguments can be satisfied.

It seems logical to assume that those who can develop an intricate process of manufacture also should have the ability to devise satisfactory ways and means of disposing of waste products. Methods are already available for the disposal of most wastes and are being adopted by many industries. Others continue to discharge raw untreated wastes into running streams with the excuse that the cost of doing otherwise is prohibitive. It is recognized that the cost of known methods for the treatment of wastes from certain industries is exorbitant, and it is also realized that other industries are so handicapped by their locations that the costs of the treatment of their wastes are abnormally high. These industries should be assisted, rather than discouraged by any sanitation program.

If possible, the streams should be surveyed and studied before over-pollution occurs and the unregulated discharge of polluting wastes becomes an established practice. The data discussed by Mr. Streeter should be gathered and assembled to form a base line of existing conditions and to provide a foundation upon which to build the necessary regulatory measures. Comprehensive plans for the proper use and conservation of this natural resource, for the prevention of its thoughtless destruction, will be far less expensive and much easier of enforcement than the later remedial measures. In the preparation and establishment of these standards and regulations, due regard should be given to the economics of the problem. It should be realized that the true development of the industries and the advancement of the area are mutually dependent upon a well-rounded program in which all factors are given full consideration. It will not be just to require that all wastes be purified to meet certain standards regardless of cost; on the other hand, the uncontrolled discharge of raw untreated wastes should not be tolerated.

For the proper solution of this problem, much research work will be necessary; co-operative studies must be undertaken in which the industries should be willing to assist. By combined effort and co-operation, new solutions may be found. Although industries have made many investigations resulting in benefits to themselves by the recovery of products formerly wasted, and in benefits to the public in the way of cleaner streams, they still have a long and difficult way to go, and a way that can best be traveled at the moderate pace now possible before speed is made necessary by an aroused public through national legislation.

Early in the history of the Tennessee Valley Authority, the need for the collection of these basic data was felt by the Health Departments of the seven Valley States. At their request, the Authority has undertaken the study with the advice of the U. S. Public Health Service and with the co-operation and assistance of the States. Although the area cannot be considered intensively industrialized at present, certain areas are highly developed and the uncontrolled discharge of wastes is seriously polluting a few of the major tributaries. With the expected development of this area, peculiarly rich in a wide range of natural resources, additional streams will be ruined and conditions aggravated unless uniform procedures applying to the entire Valley are effective. This interstate nature of the problem was an added factor which prompted the States to request the Authority to direct the studies and to act as a clearing house for the assembled information.

The work was begun in 1936. All information pertinent to the study was collected from the various State Health Departments. This consisted primarily in the extent of sewers in the various towns in the Valley. No information as to the extent or character of industrial wastes, or on the present conditions of the streams, was available. It was necessary, therefore, to obtain and correlate this information before true conditions could be pictured. At present (1938), an approximate list of industries has been collected; some have been studied in detail; and plans for the future contemplate the examination of a sufficient number of the remainder to complete the necessary data. Four sections of the Tennessee River, from which weekly samples were collected from a sufficient number of stations, to define conditions of pollution and recovery, were studied for a period of one year. These sections were at

Knoxville and Chattanooga, Tenn., and at Decatur and below Wilson Dam, in Alabama. On the completion of these studies, similar studies were undertaken on the main tributaries, some by the States, and others (for example, all field and laboratory work), by the Authority.

As in other areas where such studies have been conducted in co-operation with industries, it has been necessary to develop mutual confidence before the full value of the study can be obtained. Although the program has progressed somewhat slowly, research problems in co-operation with one of the industries was undertaken in the summer of 1938.

In the execution of this work, it is the desire of all concerned to use the resulting information co-operatively and constructively in such manner as to be compatible with the achievement of the end in view, namely, the control of the discharge of wastes and sewages to insure a balanced development of this resource; that it will not be rendered unfit for re-use by municipalities and industries located down stream; that the maximum of fish life may develop; and that a sufficient number of areas safe for recreational purposes may be maintained. Although the progress of this program, as indicated by visible results, may be somewhat slower than that resulting from more drastic action, it is expected that its achievements will be more substantial and enduring. In addition, it is hoped that this project, having an early beginning before serious conditions develop and embracing as it does the entire Tennessee Valley, will demonstrate the value of such co-operative policies and action.

DON E. BLOODGOOD,[47] ASSOC. M. AM. SOC. C. E. (by letter).—The effect of sunlight upon the dissolved oxygen in the stream is an important factor, often overlooked when samples are taken. Samples taken on White River below the City of Indianapolis, Ind., show that the dissolved oxygen may vary as much as 1.0 ppm from one side of the stream to the other, if the one side is shaded and the other is in the sun. This effect is only noted when the river is in a favorable condition for algæ growths. Samples taken at midday may have as much as 3.0 to 4.0 ppm of dissolved oxygen whereas, at night, it may drop to zero. It can be seen that samples taken during the day may not indicate the extent of pollution in a stream if the plant life in the water is abundant.

For a number of years the movement of the river water has been studied by determining the chloride concentration in the stream. The chlorides that are not removed by the purification plant pass on into the stream and, because they fluctuate from low to high with the peak flow of sewage, they are easily traceable in the stream when the ratio, of effluent to river flow, is low.

The comments by Mr. Streeter on the retardation of re-aeration by the presence of sewage in a stream are very interesting. In some work done in 1935[48] the first indications were that the saturation point of sewage with oxygen was less than that of water. This was disproved later by a further study which showed that the saturation point of sewage was the same as that of water if determined by a modified Winkler method, in which the demand for iodine was first satisfied. Whether the rate of re-aeration was slower was never determined.

[47] Supt., Dept. of Sanitation, City of Indianapolis, Indianapolis, Ind.

[48] Rept. of Dept. of Sanitation, City of Indianapolis, Ind., March 25, 1935.

W. L. Stevenson,[49] M. Am. Soc. C. E. (by letter).—The discussions and subsequent experiences during the 1937 flood in the Ohio River, strengthens the writer's conviction that preparedness is essential for protection of the public health during floods. This means pre-planned general principles of procedure, trained personnel in Federal, State, and local health departments, systematic swift mobilization of skilled men and women with essential equipment and materials, and resourceful and trained water-works operators. Experience has also shown the need for more extensive and better facilities to those charged with the duty of forecasting flood crests so that due warning may be given and safe-guarding measures adopted where possible. Of equal importance is the need for strengthening the confidence of the public in health authorities in order that there may be the fullest co-operation.

In the final analysis, it is upon the large number of lay people whose homes are in the flooded areas that the burden falls. The most that the small group of trained engineers, physicians, and nurses can do in such emergencies is to direct, guide, advise, and help.

Mr. Holmquist, writing from personal flood experiences in New York State "emphasizes in the strongest terms" the responsibility of the local authorities; and Mr. Weston refers to the serious condition that arises when local authorities lack comprehension. Many a ship reaches its port safely in fair weather, but when storms arise and the winds rage, only a trained captain and crew can save the ship. So it is in emergency sanitation during flood or disaster.

The unqualified "boil water" notices used by the Pennsylvania Department of Health during the March, 1936, floods were criticized by some water purveyors, and Mr. Holmquist discussed this question constructively. The writer maintains his position in this matter, believing that the obvious injustice to those water purveyors who remain able to serve pure water during the emergency is far outweighed by the extra safeguard to the public health of the unqualified warning to boil all water used for drinking within the flooded areas.

It was common experience to find some private water wells within flooded areas which were dominantly furnished by a piped public water supply that remained uncontaminated during the flood. Therefore, it is better for the many to boil the pure piped water supply unnecessarily than for the few to drink, unboiled, the contaminated water from the flooded private wells.

As the flood waters receded in Pennsylvania after the March, 1936, floods, one of the heaviest tasks of the State Health Department was to direct the cleansing of polluted private wells. There was nothing spectacular about this work, such as the heroic service of many employees of public water-works menaced by the flood as the rivers crested; but it was a vital part of the entire program for prevention of water-borne disease.

D. E. Davis,[50] M. Am. Soc. C. E. (by letter).—Certain threads of thought run through many of the papers presented in the Symposium, and in the comments by the various discussers, that indicate a fairly general agreement on certain fundamental concepts. It is recognized that a broad drainage area is the proper geographical unit for approaching the solution of pollution problems, and that in many instances the co-operation of several States may need to be enlisted to make this possible. State compacts appear to offer favorable mediums for action.

[50] Engr. (The Chester Engrs.), Pittsburgh, Pa.

A unified approach also offers advantages in the cleaning up of pollution in certain metropolitan districts, such as Pittsburgh, Pa., and Cincinnati, Ohio, where a number of separately organized communities are affected by similar conditions. Sewerage Boards, serving the group of communities and with power to raise money, assess costs, and collect rentals, offer a hopeful approach.

The rôle of research in defining the extent of pollution and the degree of purification required is highly essential. This tool can also be utilized in solving problems connected with self-purification in streams, as well as those of a special character having to do with the underlying phenomena of the action of acid on sewage.

Grants-in-aid by the Federal Government have resulted in a marked increase in the total number of treatment plants during the past few years, and the continuation of this policy in some form offers hope of further advances. All are agreed that the public in general is taking a keener interest in the vital job of cleaning up its streams, and that with a little encouragement a large measure of accomplishment may be expected.

Paper No. 2033

PRACTICAL METHODS OF RE-ZONING URBAN AREAS

By Hugh E. Young,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Robert D. Kohn, Myron D. Downs, Harland Bartholomew, Benjamin Saltzman, G. H. Herrold, and Hugh E. Young.

Synopsis

The purpose of this paper is to show why re-zoning is a present-day necessity, and to indicate some practical methods of re-zoning urban areas. The first part of the paper is devoted to an explanation of zoning experience in Chicago, Ill. The Illinois State law permitting zoning is outlined, together with the 1923 Chicago zoning ordinance and subsequent amendments in methods and policies, and then a comparison is drawn between land uses as they existed in 1923, the land-use allocations made in the 1923 zoning ordinance, and the land uses as they existed in 1936. The writer believes that this factual demonstration of conditions in Chicago, which are shown to be similar to conditions in other American cities, proves the need for re-zoning.

The latter part of the paper is devoted to the recent development of "measuring sticks" that can be used as guides in the allocation of land for various uses wherever re-zoning is undertaken. A real property inventory and land-use survey are advocated as the initial step. These are to show existing patterns of land use, areas of blight, population changes, and other factors which together make re-zoning necessary. In this part of the paper the technique of re-zoning is outlined, together with the tabulated result of a questionnaire dealing with the need for and method of re-zoning in about seventy-five American cities. The question of blight is dealt with in detail, as also is the matter of public and private housing; and the paper concludes with the writer's recommendation as to what he considers to be a practical method of re-zoning urban areas, particularly with regard to the rehabilitation of blighted districts.

Introduction

The fact that the need for re-zoning urban areas is being discussed means that considerable progress has already been made in zoning. In recent years

---

Note.—Presented at the meeting of the City Planning Division, New York, N. Y., January 21, 1937, and published in March, 1938, *Proceedings*.

[1] Chf. Engr., Chicago Plan Comm., Chicago, Ill.

city planners have learned much about the technique of proportioning urban use as to amount and location. It has now become desirable to adjust some of the older ordinances to a more "even keel" by means of re-zoning, and to emphasize certain principles that should be followed in the preparation of new zoning ordinances.

Engineers should not be too critical of the work of the planners of fifteen or twenty years ago, because they were pioneers and were trying to correct conditions of urban structure that had been typical for centuries. They had to re-zone men's minds as well as the physical structure of cities.

NEED FOR ZONING

Why Zone?—Many accomplishments in art and science have been achieved and great progress has been made in recent years in architecture, engineering, and public works; and yet city congestion, blight, slums, and misery are still to be found. These by-products of human activity have ever been present as a challenge to the humanitarian instincts of Man throughout the centuries. It is only in comparatively recent years, however, that city planners have come to sense the great social need of transforming the physical structure of urban areas. Zoning is a fundamental and vital element in city planning, because it is the process that co-ordinates the social, economic, and physical structure of urban areas.

Extent of Zoning.—Since 1916, when the City of New York, N. Y., was granted enabling powers by the State Legislature, approximately 1 200 zoning ordinances have been put into effect in the United States, representing approximately 75% of the urban population of the country.

Zoning Handicaps.—As a rule, planning commissions did a creditable zoning job in the early plans, considering the handicaps involved. The art of zoning was then in its pioneer state. Often, it developed that property owners on section line streets (usually the car-line streets, and other thoroughfares) insisted upon having their residential property zoned for business use. Often, too, real estate speculators, through some device or other, obtained concessions favorable to their exploitation process. Many citizens, also, were speculatively minded and hoped, by means of zoning, to have their property transformed from ordinary to high value.

Zoning Experience.—When all the comments, pro and con, have been "put in the hopper," all must agree in the final analysis that zoning has been worth while and that it was valuable during the boom building period prior to 1929, but that it is far from perfect in its present status. The art is still crude with respect to the "tapering-off" process or the transition from a higher to a lower use and the utilization of park strips between residential sections and other uses. Although present zoning plans and ordinances seem to be satisfactory in many smaller cities, officials of most cities, both large and small, feel that re-zoning is necessary. Without doubt, zoning has exercised a beneficial influence in shaping the growth of cities, and often has served as a barrier in preventing abortive property uses.

Zoning Variations.—Variations in residential areas are detrimental because they unstabilize the zoning of the block and of the district; residential protection is destroyed and competition is set up with property already zoned for business. There are innumerable examples in which miscellaneous variations of this character are permitted, and in which penetration of unsuited uses is gradually nullifying the spirit of zoning.

In some instances entire blocks of property are zoned for business where the business structures are in decay; yet only a few blocks away commercial usage has been allowed to penetrate into residential areas. If business had been confined to the area zoned for commercial use, it would have put that property into a revenue-producing position, and would have protected the residential areas, which now are certain to disintegrate, having no stabilization either for residential or business use.

There are several variations or non-conforming uses to be found in nearly every block in Chicago, Ill., for example. It is a common occurrence that if these illegal uses are carried into Court, the cases are continued ten or a dozen times, until the matter is finally dropped.

Zoning Experience in Chicago, Illinois

The administration of a zoning ordinance in a large city is a difficult task. The mayor, aldermen, and all city officials are continually bombarded with requests for variations, which ultimately reach the Board of Appeals. The Chicago Zoning Board of Appeals has shown great fortitude and patience in this job and has also demonstrated a fine understanding of the theory and practice of zoning and the need for re-zoning; but it seems impossible, in the complexity of the situation, to maintain the integrity of the zoning ordinance 100 per cent.

The Chairman of the Board, Mr. James H. Gately, is firmly of the opinion that although it is not present practice in Chicago, a certificate of occupancy is most important for the proper functioning of the zoning ordinance; but such a certificate should not be issued by the same department that is charged with its enforcement.

Protecting Manufacturing Districts.—Mr. Gately is also of the opinion that one of the fundamental safeguards to be provided for in re-zoning is reciprocal protection for manufacturing and residential areas. He feels strongly that there should be a tapering off from manufacturing to commercial to residential use in a manner that will not impose restrictions upon manufacturing development. It has been his experience that residential areas contiguous to manufacturing property are certain to be invaded by commercial use.

The City Council should not permit variations without the prior approval of the Board of Appeals. If there is disagreement, the matter should be referred back to the Board for further consideration.

The Board of Appeals should not have the legal power to break a solid block of use, even if there is a non-conforming use in the block across the street; nor should the Council exercise such authority. Proposed zoning amendments require a two-thirds vote of the Chicago City Council to become effective in the event that a written protest against such amendment is made by 20% of the people on the frontage affected, or of adjacent frontages.

Need for Buffer Organization.—The administration of the zoning ordinance is an almost continuous problem of fighting favors. A strong buffer committee is greatly needed. No variation of any consequence would ever "get by" without political backing. In other words, any proposed variation would be taken care of expeditiously by the routine of the Board of Appeals, and would be properly disposed of, were it not for political interference.

A zoning ordinance will not be effective unless its administration is in strong hands, free from political domination. The essential need is a strong public body, such as a plan commission, to lend support to the Zoning Board of Appeals. In fact, a city plan commission is as essential as a Board of Appeals in preserving the integrity of the zoning ordinance.

Zoning Situation in Chicago.—The main purpose of the Chicago Zoning Ordinance was to protect property devoted to its highest and best use against sporadic invasion of uses which would tend to destroy the taxable value of land and buildings and impair public health, safety, comfort, morals, and welfare. In large measure, however, the ordinance has failed to provide this protection. It was not retroactive and, therefore, could not protect neighborhoods against undesirable developments already in existence.

Visions of enhanced realty values from commercial uses and greater height and volume provisions resulted in public demands for zoning classifications obviously out of line with actual and prospective land and building use. Ordinance provisions permitting additional non-conforming uses were not sufficiently strict to assure districts remaining in the class in which they were zoned. Broad discretionary powers were granted the Zoning Board of Appeals to permit variations in case of practical difficulties or particular hardship.

Chicago Zoning Provisions.—The Chicago Zoning Ordinance provides four "use" and five "volume" districts. The use districts embody residence, apartment, commercial, and manufacturing districts. The volume districts regulate and limit the height and bulk of buildings and the intensity of the use of land, the height limitations ranging from 33 ft in Volume District No. 1 to 264 ft in Volume District No. 5.

Illinois Zoning Law

The Illinois law provides for the establishment of Zoning Boards of Appeal and gives them power to: (1) Interpret the terms of the zoning ordinance or the application as made by the building commissioner; (2) vary the application of the ordinance in special cases of unnecessary hardship; and (3) recommend to the City Council changes in the zoning ordinance.

The State law does not grant Boards of Appeal the power to change a zoning ordinance or to change the classification of property under the zoning plan, but confines the power of amending the ordinance to the City Council.

1934 Amendments.—In 1934, the section of the Chicago Zoning Ordinance of 1923 dealing with the Board of Appeals was amended by the City Council to specify who should be eligible to membership; to provide for board members serving without compensation; and to incorporate certain provisions of the State Act with respect to appeals. In addition, about eighteen variations which the Board might make in specific cases of hardship were enumerated.

The power of permitting variations is in such general terms that it affords the possibility of grave abuse. No standards are defined to guide the decision of the Board, but judgment is left almost entirely to the Board's discretion. For example, the zoning ordinance specifically provides that no manufacturing use shall be permitted in a commercial district. The 1934 amendment authorizes the Board to grant permission to devote premises in a commercial district to a manufacturing use where the appropriate use of neighboring property is not injured thereby.

Variations of this character may be right and necessary to prevent hardship, even if they are in direct conflict with the language and purpose of the zoning ordinance; but there is a strong possibility of abuse by unreliable Boards when the Board constitutes the sole judge as to whether or not the non-conforming use is injurious to neighboring property. In the hands of an undependable Board the variations permitted may easily amount to such a volume of precedent as practically to nullify the purpose and intent of the entire ordinance.

Present Use Factor.—In developing the need for re-zoning, the most practicable "measuring stick" appears to be the factor of use. The research already made in this direction is of tremendous importance. Significant comparisons can be made based upon conditions in Chicago.

Fig. 1(*a*) shows the use of property in Chicago as of 1923 when the zoning ordinance was passed. At that time, the incorporated area was 201 sq miles and comprised the uses shown in Table 1(*a*). The developed area comprised 143 sq miles. The remainder of the area (58 sq miles) was occupied by water, or was vacant.

TABLE 1.—LAND USE IN CHICAGO, ILLINOIS

Uses	(*a*) AS OF 1923		(*b*) AS ZONED IN 1923		(*c*) EFFECT OF SUBURBAN FACTORS	
	Area, in square miles	Percentage of incorporated area	Area, in square miles	Percentage of incorporated area	Area, in square miles	Percentage of developed area
Single-family dwellings	23.75	11.8	5.91	2.9	62.25	26.6
Two-family dwellings	15.66	7.8	38.55	19.1	18.70	8.0
Multiple-family dwellings	9.19	4.6	26.00	13.1	15.98	6.8
Total dwelling areas	....	24.2	....	35.1	....	41.4
Commercial areas	9.87	4.9	28.24	14.0	13.61	5.8
Manufacturing areas	25.91	12.9	48.64	24.1	34.45	14.7
Special areas	4.95	2.4	....	....	11.92	5.1
Streets and alleys	46.60	23.3	46.60	23.3	69.30	29.6
Parks and playgrounds	7.06	3.5	7.06	3.5	8.06	3.4
Water and vacant property	58.01	28.8	....	....	....	....
Total	201.00	100.0	201.00	100.0	234.27	100.0

Fig. 1(*b*) shows the manner in which the area was zoned in the 1923 ordinance. The entire area of 201 sq miles was zoned for the uses indicated in Table 1(*b*). All vacant areas were defined for use of some character. Water areas were zoned for the same use as contiguous areas. A comparison of Figs. 1(*a*) and 1(*b*) shows that, although the zoning ordinance increased the total dwelling areas 1.45 times, the single-family dwelling areas were decreased to less than one-fourth the space then in actual use. Commercial areas were increased 2.86 times, and manufacturing areas were increased 1.88 times the space then in actual use.

Actual and Zoned Use Situation in 1936.—At the close of 1936, there had been little actual change in land use despite the great increase it was originally assumed would take place in manufacturing and industry. In the last thirteen years of that period 100 539 building permits were issued, which, translated into land use, is shown in Fig. 1(*c*). During that period an estimated total of 21 965 permits was issued for demolition of property, which number, translated into shrinkage of use, shows a decrement of 3.15 in percentage of developed area. The net percentage of added developed area occupied during the 13-yr period for dwelling purposes was 8.0; for commercial areas, 1.9; and for manufacturing areas, 0.46.

Number of Variations.—For this same period a number of variations occurred in the zoned use, the net interchange in the developed area (see Fig. 1(*f*)) being: An increase of 0.55% for total dwelling areas; an increase of 0.60% for commercial areas; and a decrease of 0.21% for manufacturing areas.

The graphs in Fig. 1 are of interest in that they show little agreement with the absorption of use as predicted in the 1923 ordinance. There was little change in the areas actually devoted to commercial and manufacturing use, which uses were provided for, generously, in the original ordinance.

Residential vs. Business Use.—Residential use, which was assigned the least area for expansion, showed the greatest development in the period. Demolition has not helped the situation because the largest areas thrown into disuse are commercial and manufacturing, and those are the areas that were assigned the greatest percentage of use in the 1923 ordinance. The trends are somewhat irrational, of course, because of the interrupted normal use absorption resulting from the depression years from 1929 to 1935. Considerable recession has occurred in the use of railroad and manufacturing property.

The Situation as a Whole

The percentage of developed area occupied by various land uses applies only to the area within the city limits, which does not, of course, give the "true picture" for determining the land use factors for Chicago as an entity. In order to have a proper comparison with other self-contained cities, the data should include the suburbs, because they are largely residential areas for the workers of Chicago.

Fig. 2(*b*) shows the developed area of Chicago in 1936 within the city limits, amounting to 157.77 sq miles, and Fig. 2(*a*), the developed residential areas beyond the city limits, comprising 76.50 sq miles.

Suburban Factors.—Only those suburbs have been included in this study that are integrally a part of Chicago even if located outside the corporate limits. Indicating the use for "Greater Chicago," as shown in Fig. 2, the present land uses, in percentage of developed area occupied, are as listed in Table 1(*c*).

Comparison with Independent Survey.—In Fig. 2(*d*) is shown the corresponding percentage of developed area occupied by various uses in sixteen self-

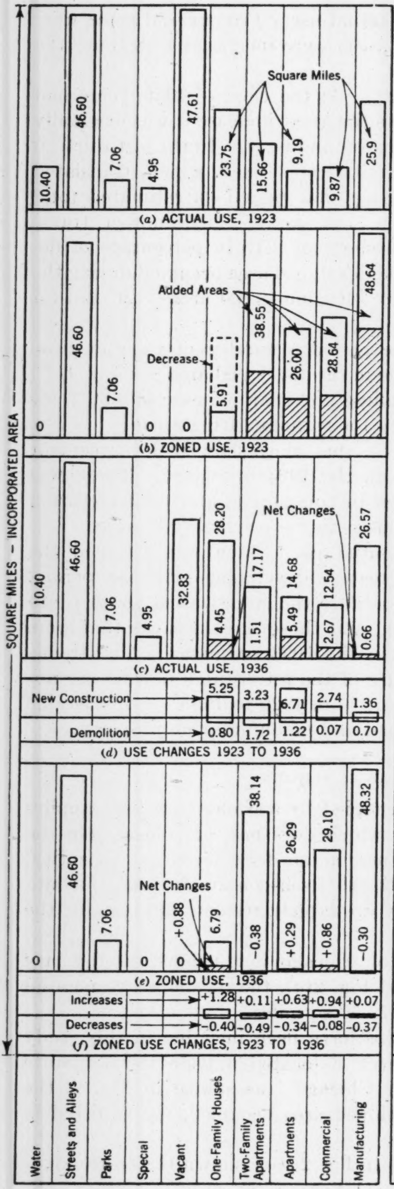

FIG. 1.—LAND USE IN CHICAGO, ILLINOIS

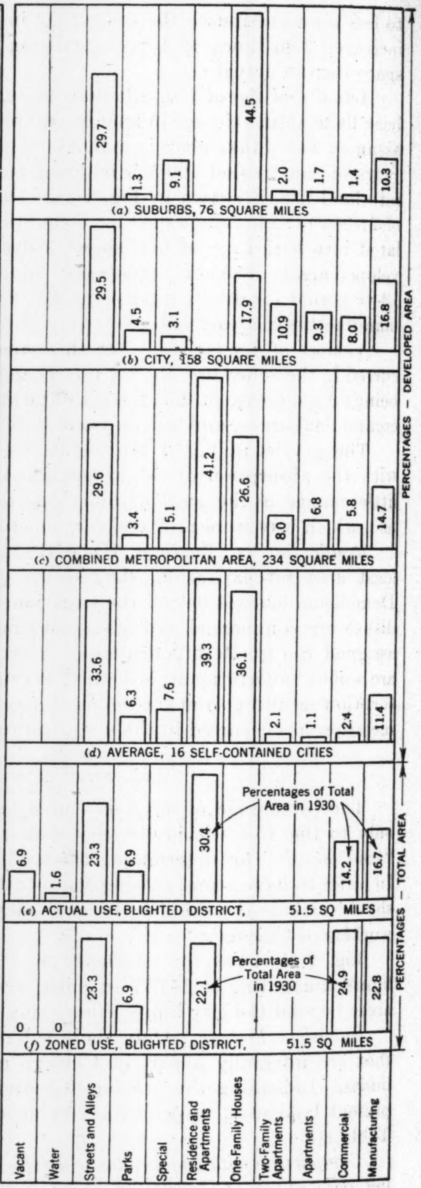

FIG. 2.—PERCENTAGES OF DEVELOPED AREA, CHICAGO, ILLINOIS

contained cities as disclosed in a survey made by Harland Bartholomew, M. Am Soc. C. E.[2] It will be noted that the percentages of occupied developed area in these sixteen cities and in Chicago are in very close agreement (see Fig. 2(*c*)). This indicates that factors determined by his survey are applicable to large urban areas, such as Chicago, with the exception of the classification of residential use. In Chicago, and probably in other similar cities, a much greater percentage must be allowed for two-family and apartment house use, and a shading of use for single-family dwellings. The ratio of all land-use areas to population, in terms of acres per 100 persons, can readily be determined from these percentages.

When the information developed by land-use surveys of other large urban centers has been compiled in terms of percentage of area developed for the various uses, city planners will have a valuable means of allocating city area, definitely, for various uses and for different classifications of city population. Therefore, any city, after it has reasonably determined its prospective future population, can zone properly for present use and can determine the proper proportion of future use absorption.

Zoning Mistakes.—When the present use of property in Chicago is compared with the zoned use, and it is found that after thirteen years practically none of the increased use anticipated in 1923 has occurred, one cannot escape the conclusion that present zoning methods are badly distorted and that Chicago must be re-zoned.

Zoning in Chicago is not only distorted with respect to an illogical allocation of usage, but also with respect to the distribution of various uses. Little consideration has been given to tapering off from highly restricted uses to unrestricted uses. There is a lack of buffer property between manufacturing use and residential use.

Chicago (and perhaps other cities as well) arbitrarily zoned major and minor streets in checker-board fashion for commercial use, and zoned areas for residential use contiguous to manufacturing use. It will be necessary to delete miles of such commercial zoning and to replace it with residential use. Furthermore, it will be necessary to re-zone areas contiguous to manufacturing property from residential to commercial use.

"Blue-Sky" Zoning.—"Blue-sky" zoning has complicated the tax machinery. If valuations are based on the present value of hundreds of miles of fictitiously zoned commercial property, where because of its blighted nature there is no income, this cannot possibly mean anything except tax delinquencies. This also applies to many areas that have been zoned for large volume residential property. The deficit thus produced must be made up in some other manner.

Surveys in Cleveland, Ohio, New York, N. Y., Boston, Mass., Los Angeles, Calif., and other cities give volumes of information on this subject. As a matter of fact, improper zoning is a blight in itself, in that it specifies a use and volume that can never be attained. While awaiting the advent of such expected use the property is often allowed to fall into disuse because it does not seem worth while to spend the money to keep it in condition for its former use.

---

[2] "Urban Land Uses," by Harland Bartholomew, Harvard Univ. Press, 1932.

Re-zoning beyond the urban limits is also necessary, if for no other reason than the need of safety. The removal of the "honky-tonk," mushroom growth of "hodge-podge" commercial uses that now clutter the main highways and create a dangerous marginal friction, can be accomplished by pushing these uses, where needed for the local community, back of the highways in a manner similar to that being done on highways in some foreign countries.

Re-Zoning Needs.—One notable example in Chicago of the impropriety of zoning residential areas near manufacturing areas is the Trumbull Park Homes Project of the Public Works Administration (PWA) in the South Chicago industrial district. This is an area of 21.5 acres, the approximate boundaries of which are Trumbull Park, Bensley Avenue, and the Chicago and Western Indiana Railroad. The housing project is located in the very heart of a large manufacturing area. The Government asked for a revision in the zoning ordinance, but when it was discovered that if this area were re-zoned for residential use it would immediately render all industrial property within 2 000 ft of it useless for certain manufacturing purposes similar to those now there, the request for this zoning revision was withdrawn, although the housing project was continued.

Manufacturing property needs protection just as much as residential property, and this protection would seem to be the utilization of contiguous areas for commercial use, tapering off into residential use, the latter being removed far enough from manufacturing areas so as to avoid restricting the free use of such manufacturing areas. There is also opportunity in this buffering process for an appropriate interposition of needed park areas between residential and commercial use.

Comparison with a Hotel.—A city is a corporate entity that should be as susceptible of the intelligent application of economic principles as any business corporation. Consider a hotel, for example, and apply to it the factors of Chicago's zoning: 52% of the hotel's floor area was zoned for show rooms, restaurants, and other commercial uses, including its operating facilities, whereas only 39% of the total floor area was being used for these purposes; only 4% was zoned for single rooms, whereas 29% was being used for this purpose; 26% was set aside for double rooms and only 17% of the area was actually being so used; and 18% was zoned for suites whereas only 15% of the normal hotel area was actually being so used. Every one must appreciate how illogical such a condition is when applied to a business corporation; but few people seem to realize that it is equally illogical when applied to a municipal corporation. The proper basis for zoning is the present use factor, and anticipated future absorption of vacant property must be provided for on the basis of this factor.

BLIGHT

Description.—In the larger cities, at least, re-zoning is essential before blighted areas can be rehabilitated. This is the situation in Chicago, where the blighted district is twice the size of Manhattan Island, New York. It is the backyard of the lake-front development, and stretches virtually from Belmont Avenue on the north to 63d Street on the south, and from the "Loop" west to Kedzie Avenue. This comprises a total area of 51 sq miles, of which 44 sq miles are blighted territory. In this district, which is about one-fourth the total area of all Chicago, live two-fifths of the city's population—about 1 300 000 people. The district contains 169 000 families of the lowest income levels. Maps of this district, prepared by the Chicago Plan Commission in collaboration with the Social Science Department of the University of Chicago, show that the density of population in the 287 census tracts in the district are as given in Table 2.

TABLE 2.—DENSITY OF POPULATION, CHICAGO, ILLINOIS

Population density in persons per acre	Number of census tracts	Percentage of total
Less than 30	23	8.0
30 to 60	106	37.0
60 to 90	111	38.7
90 to 120	43	15.0
120 to 150	4	1.3
Total	287	100.0

Use Data.—Comparing the 1930 use map of this area with the zoned use, the condition is as shown in Figs. 2(*e*) and 2(*f*). The effect was to decrease the population in total dwelling areas, 27%; increase it in commercial areas, 75%; and increase it in manufacturing areas, 37 per cent. These data certainly are a strong argument for re-zoning this area. The need for rehabilitation of the area is emphasized by the fact that 70% of the district is occupied by frame structures from 30 to 60 yr old.

Home Ownership.—To what extent do the residents of this section own the homes in which they live? In the 414 census tracts of the 1930 Census the distribution is as shown in Table 3. In 72 tracts less than 10% of the families own their own homes.

TABLE 3.—HOME OWNERSHIP

EXTENT OF HOME OWNERSHIP; RANGE OF PERCENTAGES		Number of tracts	Percentage of total tracts
From:	To:		
	<1	4	1.0
1	9	68	16.5
10	19	94	22.7
20	29	123	29.7
30	39	75	18.1
40	49	31	7.5
50	59	11	2.6
60	69	8	1.9
Total	....	414	100.0

TABLE 4.—RENTALS

RANGE OF AVERAGE MONTHLY RENTALS		Number of tracts	Percentage of total tracts
From:	To:		
*	*	4	1.0
$10	$19	37	9.0
20	29	140	34.0
30	39	97	23.5
40	49	87	21.0
50	59	22	5.2
60	69	18	4.2
70	>70	9	2.1
Total	....	414	100.0

* There are no homes in these tracts.

Rentals.—In the 414 census tracts of the 1930 Census, the median rental values were as shown in Table 4. The living quarters in one-third of the census tracts in the district yield an average monthly rental of $40, or more, and the living quarters in two-thirds of the tracts yield only from $10 to $39 per month.

The zoning volume regulations in this district are such that a building height of 66 ft at the street line and 132 ft maximum with set-backs, may prevail in more than one-half the area.

Population Changes.—One of the effects of blight and an indication of its presence, is the mass movement of residents away from a district. The boundaries of the territory of principal population decline of Chicago, 1920–1930, shown by the broad black band on Fig. 3, coincide generally with the boundaries of the blighted district. This district contained 1 060 716 residents in 1920. In the 10-yr period it lost 146 354 people, or 13.8%, leaving 914 362 people in 1930.[3] In the next four years the decline continued, the population dropping to 848 803. The total decline in this area for the 14-yr period amounted to 211 913, or nearly 20 per cent. In 1934, the boundaries of the territory of principal population decline had moved outward as shown by the broad black line on Fig. 4. The 1920–1930 territory of decline is shown bounded by a heavy broken line. The territory between these two lines contained 1 633 596 people in 1930. In 1934, this number had declined to 1 563 505, a loss of 70 091 residents, or 4.3 per cent. The 4-yr loss of the original district shows a population decline of 282 004 for both areas. Until the years 1920 and 1930, respectively, these areas had shown a steady increase in population.

Rehabilitation of Blighted Areas.—Blighted areas in Chicago must be rezoned regardless of any particular method that may be adopted for financing their reconstruction. Some of the sources of blight are the following: (1) Decentralization and moving away of factories and industries; (2) public improvements that provide outlying developments which induce the higher paid residents of a district to abandon the old and move out to the new; (3) faster transportation that enables people to live farther away from their place of employment; (4) retention of old unfit housing and lack of suitable housing facilities for lower income groups, resulting in over-crowding of run-down districts; (5) single-family dwellings occupied by a multiplicity of families; (6) removal of the established residents and the incoming of new residents with less civic interest and generally with less income; and (7) depreciated land values; weak owners; repeated change in ownership; lack of adequate maintenance because of surrounding dilapidation and fear of what adjoining property owners might do that would still further depreciate values and income.

Annual Deficits.—If city expense in Chicago were pro-rated on the basis of area and compared with revenues received from the blighted districts, the results would be a deficit of tens of millions of dollars, assuming that all taxes were paid. As a matter of fact, there are 24% delinquencies in tax payments, so that if the deficit was paid by 10% of the city area, including the high-class business and residential property, as was shown to be the case by a survey made in Boston, Mass., that fact should be some incentive for the city's leaders of industry, business, and commerce, to devote more attention to the rehabilitation of blighted areas.

---

[3] "Census Data of the City of Chicago," 1920 and 1930 Rept., Social Science Dept., Univ. of Chicago.

The question is always raised: "How can water be made to run up hill?" The answer is to be found in two fundamental factors: First, vital consideration of the sources of workers' income; and, second, the ability of workers to pay rentals for living quarters of not less than "low-cost" housing standards.

Manufacturing Removals.—For years there has been a recession of manufacturing use and the contingent sources of labor, such as railroad service, etc., in the areas adjacent to the "Loop," in Chicago. The West Central Association in Chicago stated in 1936 that:

> "$30 000 000 is a conservative estimate of the amount of business which is driven away every year by the lack of good transportation arteries, the disintegration of neighborhood areas and other causes which have brought about the dry rot which has been steadily eating into the entire west side section during the last twenty years. One business concern after another is forced to move into other districts where more favorable conditions are available. In the five years between 1924 and 1929, seventy-five large industries moved from the west side to the outskirts of the city."

Manufacturing must be encouraged to remain in blighted areas. These plants must be given protection against such zoning of contiguous areas as will restrict manufacturing expansion. New manufacturing concerns must be induced to locate in blighted districts because this is an essential means of stabilizing these fast deteriorating areas. Adjustments must be made in tax valuations to bring tax rates in blighted districts down to a level as favorable as that in effect on the outskirts of the urban areas.

Income Needs.—People cannot live in any kind of housing conditions without an income. A. C. Comey, M. Am. Soc. C. E., has described the situation pointedly:

> "A slightly different approach to population planning is afforded by combining it directly with a study of activities, largely expressed in terms of numbers of people. Thus we may inquire not merely where people have been, are, and are likely to be, but also why. * * * Pursuit of livelihood is a most compelling reason "why," for most of the population."

The problem of a standard minimum wage is a national one, but it is evident that the income of a family gainfully employed cannot be less than, say, five times the rental of "low-cost" housing. Rentals, of course, will vary in different sections of the country.

There are two important factors involved, therefore, in the rehabilitation of blighted areas. In some manner, present manufacturing will need to be induced to remain in blighted areas, and should be given opportunity to expand its plant by proper zoning; additional diversified manufacturing and industry will have to be induced to locate in these districts; and it is evident that the income of a family gainfully employed must be such as to permit it to live in dwellings of not less than standard low-cost housing.

The rehabilitation of blighted areas has been an enigma for many years, and it will continue to be an insoluble problem unless these two factors are properly determined, although they seem very commonplace in the array of panaceas that have been advanced for social betterment.

FIG. 4.—POPULATION TRENDS, CHICAGO, ILLINOIS, 1930 TO 1934

What Do the Studies Show Further?—Referring once more to the studies made, it is interesting to determine what they show with respect to blight and the need for re-zoning. They show that:

(*a*) In Chicago there are 44 sq miles of blighted territory piling up enormous deficits every year, which deficits must be met by the owners of property in other areas. The owners of property in this area are paying a very small share of taxes annually because they have allowed their property to depreciate and do not keep it in a condition that would give it adequate value to bear its proportionate share of city expense.

(*b*) These blighted areas may have had some prospect of development before zoning, but their prospects are now stationary because they are improperly zoned. They must be re-zoned; and there must be enforcement of demolition orders when owners refuse to make repairs, renewals, etc., necessary to make their property habitable in accordance with minimum living standards.

(*c*) The zoned use of these areas is entirely out of line with the use shown to be possible by the application of normal use absorption factors.

(*d*) There are miles of spurious commercial frontage and the pattern of location is irrational. Fortunately, little has happened in Chicago to change the "picture" since 1923. Hence, Chicago can be re-zoned in accordance with present standards without changing anything more than the zoning plats.

A Practical Method of Re-Zoning

When it comes to a practical method of re-zoning it should not be necessary to argue in behalf of the necessity of a land-use survey as a first step. Sixty-four surveys have been made in the United States and, no doubt, many more are under way. Most city planners are familiar with the startling disclosures made by these surveys.

If comprehensive land-use surveys cannot be financed, reasonably good results in fact-finding can usually be obtained from census data, use of insurance plats, assessors' cards, and other data on file in city departments.

Re-Zoning Plan.—The second step, of course, is the preparation of the official re-zoning plan based on fundamental use factors, determined from the survey and thoroughly diagnosed with respect to the average use factors of other cities. Officials have carefully estimated the future population growth of all cities so that, by applying the ratio of use per 100 population, a final total percentage of developed area can be arrived at for each use. Some cities probably have sufficient vacant property to accommodate future requirements. If not, the application of the use factors will give them a good idea of the additional area that should be incorporated. The process then becomes one of intelligent allocation of proportioned use areas.

Manufacturing Areas.—The location of manufacturing areas will be largely determined by transportation facilities. The zoned areas for this use should be checked off, and increased or decreased in size according to the use factors, but not changed in location, if the original zoning was logical. In Chicago, the location of the manufacturing areas would not be substantially changed in any re-zoning plan.

Commercial Areas.—Of course, all existing important commercial centers, areas, and frontage of major street intersections will be included as routine re-zoning. Vacant commercial frontage should be eliminated from the area zoned for commercial uses unless shown to be needed by the use absorption factor.

In allocating surplus area for future expansion of business, two important factors are involved: (1) Commercial use should be interposed between manufacturing use and residential use; and (2) proper provision should be made for proportioning the expansion of present live commercial areas. The foregoing process should proceed until the total anticipated use is absorbed.

Apartment Areas.—Multiple-family residential use should be zoned for major and minor arterial frontage. In the process of rehabilitating the blighted district these thoroughfares should receive appropriate design and cross-section development as part of the reconstruction project.

Residential Areas.—Two-family and single-family dwellings in general should occupy areas buffered by multiple-family use, parks, and commercial areas.

In examining the map of Chicago's blighted district, one may see how these factors can be applied in re-zoning the area without upsetting anything more than the 13-yr-old pages of the original zoning ordinance. Nothing much has happened since 1923 to change the "picture."

The next step, of course, is the publication of the proposed re-zoning plan, with a complete disclosure of the social, economic, and physical conditions involved and the advantages to be gained by the proposed re-zoning. That should be followed by a campaign to inform the citizens as to the benefits to be derived from re-zoning.

Summary of Answers to Questionnaire.—On December 18, 1936, the writer circulated questionnaires to 154 cities, and 102 replies were received from cities having a total population of 26 689 000, or more than 22% of the entire 120 000 000 population of the United States. The purpose of the questionnaire was to reveal the zoning situation as it exists in cities throughout the nation. This is adequate to give a true cross-section of the zoning situation throughout the entire United States. The data developed by the questionnaire are shown in Table 5.

Of the 102 cities that replied, 88 are zoned and 14 are not zoned; of the 88 zoned cities, 59 declare that re-zoning is necessary and 29 state that it is not necessary in their particular cases. Of these 88 cities, 9 have been re-zoned, according to the replies, whereas 37 others have been partly re-zoned, a total of more than one-half the entire number.

Of the 77 cities with less than 250 000 population, 39 feel the need for re-zoning, and 27 do not. Ten cities did not express an opinion one way or the other. In cities of this class the sentiment seems fairly evenly divided. In the 25 cities of 250 000 population and more, 20 report that re-zoning is needed, 2 that it is not needed, and 3 did not reply. Thus, it seems clear that the need for re-zoning is much more evident in cities of more than 250 000 population. Of these 25 larger cities, two have already been re-zoned and 10 others have been partly re-zoned. The purpose of the questionnaire was to determine the best method of gaining public approval for re-zoning. The question was propounded in the form of four alternatives.

Public Approval for Re-Zoning.—Question 4 asked if public approval of re-zoning should be based entirely upon the general advantages to be derived; that is, is re-zoning desirable?

TABLE 5.—RESULTS OF QUESTIONNAIRE TO DETERMINE THE ZONING SITUATION

CITIES GROUPED ACCORDING TO POPULATION (IN THOUSANDS)		No. of questionnaires mailed	No. of replies received	(a) NEED FOR RE-ZONING						(b) METHOD OF RE-ZONING										
				No. of cities zoned	No. of cities not zoned	Need for Re-Zoning		No. of cities re-zoned	No. of cities partly re-zoned	Question 4		Question 4(a)			Question 4(b)			Question 4(c)		
From	To					Yes	No			Yes	No	First choice	Second choice	Third choice	First choice	Second choice	Third choice	First choice	Second choice	Third choice
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)	(13)	(14)	(15)	(16)	(17)	(18)	(19)	(20)	(21)
50	100	74	47	36	9	24	17	4	21	40	0	36	0	2	5	12	16	7	15	10
100	250	47	30	27	3	15	10	3	6	20	0	22	1	1	3	6	11	3	12	3
250	500	22	15	14	1	12	1	2	6	13	0	13	0	0	0	5	3	0	3	5
500	1 000	8	7	7	0	6	1	0	2	6	0	6	2	1	1	1	3	2	2	1
1 000	>1 000	3	3	2	1	2	0	0	2	3	0	3	0	0	0	0	0	0	0	0
Total	....	154	102	88	14	59	29	9	37	82	0	80	3	4	9	24	33	12	32	19

Eighty-two cities voted "yes" on this question. No city voted "no." Thus, in 100% of the cities replying, the correspondents felt that after the re-zoning plan had been completed as outlined, public and official approval should be sought on the basis of the benefits disclosed by it, with property owners being given the opportunity to voice objections, so that provision could be made for special conditions.

Re-Zoning for Highest and Best Use.—Question 4(*a*) asked if public approval of re-zoning should be based on the argument that by reducing the area overzoned for commerce, industry, and apartment use, the value of the areas properly zoned for these purposes would be increased as a result of such limitation; that is, that the smaller area for each use would increase land values.

Replies to this question were received from 87 cities. Of this number 80, or 92%, chose this method as being preferable to the remaining two alternative methods suggested in the questionnaire. Three cities picked Method 4(*a*) as their second choice; and four others picked it as their third choice.

Among cities of less than 250 000 population, 93% of those answering the questionnaire selected Method 4(*a*) as being the best; 5% of the cities selected it as their third choice; and 2% selected it as a second choice.

Upon the adoption of an official re-zoning plan there would be a logical basis for the establishment of valuations for taxation purposes, that would be consistent with the actual development of an income from property. This is a condition that is now impossible in large sections of the United States. To-day, all property is menaced because of lack of stability. In the long run, even without intensive rehousing, the corporate fund will benefit if property can be placed in its proper class of highest and best use for development, and will be stabilized through the logical forces of use requirements which operate gradually to force development, following the law of supply and demand. For this to be effective, however, variations (the "worm" that is now destroying the "fabric" of zoned use) must be exterminated by a strong city planning and housing council.

Paternalistic Method of Re-Zoning.—Question 4(*b*) asked if public approval of re-zoning should be sought because of the value of rehabilitating blighted districts through governmental financing; that is, by paternalistic methods.

Replies were received from 66 cities. Of these, 9 selected it as their first choice; 24 selected it as second choice; and 33 selected it as third choice. Thus, only 14% considered it to be of first importance, 36% of second importance, and 50% of third importance. Among cities of less than 250 000 population, 15% considered Method 4(*b*) to be the best; 34% ranked it as their second choice; and 51% felt it to be their third choice. Thus, the smaller cities clearly feel Method 4(*b*) to be the least desirable of the three alternate methods suggested. Among cities of 250 000 population and more the vote on Method 4(*b*) *versus* Method 4(*c*) for second and third place, respectively, was fairly even.

Non-Paternalistic Method of Re-Zoning.—Question 4(*c*) asked if public approval of re-zoning should be sought because of the value of rehabilitating blighted districts through non-paternalistic methods, such as some form of trustee plan, limited dividend corporation, public utility housing corporation, or other private organization, aided by governmental financing, but not under governmental control.

Sixty-three cities replied to this question. Of this number, 12 cities, or 19%, selected Method 4(*c*) as their first choice; and 32 cities, or 51%, selected it as their second choice. Thus, among all the cities voting, the majority selected Method 4(*c*) as representing their second choice among the three alternative methods.

The Housing Situation.—Summarizing the general housing situation one finds that:

(*a*) The Reconstruction Finance Corporation (RFC) was established in 1932, with power to issue building loans for limited dividend housing projects subject to State or municipal housing approval.

(*b*) The Public Works Administration (PWA) began its housing program in 1933 by making loans to limited dividend housing corporations initiated by the RFC. Seven projects were financed in this way. The PWA turned to Federal construction, under which plan fifty projects were undertaken.

(*c*) Since December, 1934, 20 States have enacted housing legislation in accordance with drafts submitted by the PWA, providing for the creation of housing authorities that have broad powers to undertake and operate housing projects, but which are without taxing power. The authorities are given the right to secure property by eminent domain.

(*d*) Now (1938) the PWA is decentralizing public housing and turning over to the State and local housing authorities the responsibility of initiating, constructing, and operating low-rent housing projects.

Housing Needs.—The following items should be kept in mind in determining the problems of the State and local authorities in attempting to initiate, construct, and operate low-rent housing projects: (1) The enactment of enabling legislation; (2) it is necessary for the municipality to furnish the housing authority with sufficient money to defray its first year's administrative and overhead expense; (3) municipalities should be empowered to grant various forms of assistance to the housing authority, in addition to tax exemptions; (4) municipalities might find it necessary or expedient to sell, lease, or donate property to the authority to furnish parks, playgrounds, and other facilities, and to re-zone or re-plan affected areas; (5) it will frequently be necessary in connection with the financing of housing projects for long-term agreements to be entered into between the housing authority and the municipality regarding the furnishing of services and payments therefor in lieu of taxes; (6) to accomplish Objectives (1) to (5), the PWA is suggesting the enactment of the housing corporation law; (7) the PWA will operate fifty housing projects; (8) it is suggested that under appropriate and effective State legislation these projects be leased or sold to local housing authorities as soon as possible; and (9) it is also suggested that, in the future, all low-rent housing projects should, in general, be undertaken by local housing authorities on a loan-and-grant basis.

The proposed plan apparently obviates some of the difficulties of the former plans for financing low-cost housing, in that the municipal housing authority is given the right to acquire property by eminent domain.

Modification of Housing Plan.—Would it not be well to consider some modification of present and proposed legislation whereby property owners and mutual interests could assemble their property into an equity or community trust and construct, own, and administer low-cost housing properties with the aid of a Government loan and grant, subject to all the requirements to be imposed by the municipal housing authority under the present arrangement? Such a plan, of course, should be based upon a limited return on the investment of the property owners. From a purely social point of view this would be much better than the present condition in which slums are subsidized by draining municipal treasuries.

A co-operative trustee plan through this kind of financing would make possible the development of much greater areas for low-cost housing than is possible under the present plan, because of the pooling of the property itself in the development. The municipality would be much better off in the long run, because it would receive revenue from a much larger area than is possible under the present plan, as rehabilitation could be made much more extensive.

Criticism of the plan because it would involve a Federal grant to a co-operative society for private profit should take into consideration that the subsidy would be for a public purpose. It has certain "strings" attached to it in that the equity trust must be operated for limited profits and must achieve low rentals consistent with those necessary to reach the levels of the standard low-cost housing. The trustee plan would employ labor and stimulate industry on a much larger scale than would be possible with the same expenditure of funds under the housing authority.

There is objection to the Government housing authority as the only means of developing housing because it weakens private initiative. This is avoided in the equity trust plan as the property rights and control would remain with the individual owners. Maintenance and operation would be more efficiently administered under the equity trust than under political control; taxation problems would be clarified, and the public would be free from the ever-growing expense of amortization due to obsolescence.

Prime requisites for this kind of plan would be re-zoning, and the selection of cities where manufacturing use exists to give employment to occupants of housing projects.

Some Opinions

Many people are not in favor of paternalistic housing projects. For instance, Clifton R. Bechtel, Chairman of the City Planning and Zoning Committee of the Chicago Real Estate Board, writes:

> "The Chicago Real Estate Board has based its plan on co-operative individualism. There is nothing new or original about this. It came to Illinois with the first settlers. The individual stood on his own feet and carried on alone as far as he could go, and when the job was too big, he called in the neighbors and finished the job.
>
> "Our Committee feels the place to start is with the people who own the land. They feel paternalistic policies are bad, in that they tend to weaken the citizen. Many proposals are advocated as emergency measures, but even emergency measures should be carefully scrutinized."

Chicago Real Estate Board.—Some of the points of the rehabilitation plan advocated by the Chicago Real Estate Board are:

> "To arouse local public opinion and public spirit so the people themselves—the property owners and residents—can participate in the action."

* * * *

> "To aid in working out the problem along sound economic lines as a commercial and not as a philanthropic proposition."

* * * *

> "To ascertain the kind of people to live in the district; to consider those now living there; to consider those who might be induced to go there. This would mean taking into consideration the earning power of these people in making housing plans that, in cost or rentals, will fit their average income."

Lack of Private Capital.—Attempts have been made in the past to create equity trusts for the purpose of developing low-cost housing areas in which individual property is assembled into large holdings; but there has always been the complication that private capital could not be induced to take the risk because of the many unstable conditions inherent in the proposition. These conditions include instability of low-cost housing areas relative to adjacent areas and uses; the availability of employment for residents; and the ability of residents to pay the rent in such low-cost housing when constructed.

If a region is re-zoned, however, manufacturing is retained and invited to come into the blighted district, and low-cost housing projects are built in appropriate areas relative to manufacturing. There will then be large areas for residential development for housing the higher income groups along the main thoroughfares crossing the district; and it is in these areas that the assembling of property into an equity trust for ownership management and operation, or for any private undertaking, might be conducted with success, because of the stability the district would gain under the new setting.

Limited Profit Agencies.—There is also the possibility of pooling property interests in an equity trust that could obtain funds as a limited-profit housing agency, at interest rates not less than the going Federal rate. The limited-profit housing agency would be required to maintain the low-cost character of the housing, and, therefore, would not come into direct competition with private building enterprise.

The plan of pooling property interests in the formation of a limited profit housing agency would make possible low-cost housing on a much larger scale than any other co-operative limited-dividend corporation, because the Government funds would be available for costs other than that of acquiring the land.

COMMENTS ON QUESTIONNAIRE

Many interesting comments were made on the questionnaire previously referred to, among which the following were most valuable:

(1) Zoning is useful in protecting new sections from blighting influences; but alone it can accomplish little in rehabilitating run-down sections. It cannot be done intelligently unless correlated with a comprehensive city plan.

(2) Re-zoning is needed not so much to protect and increase value as to protect amenity and stability which, in turn, will be reflected in future value. Residential owners want protection of the character of their neighborhoods. Business property owners want reasonable opportunity to use their real estate profitably, consistent with the governing law of supply and demand.

(3) In re-zoning an attempt should be made to meet the following ratios: Highways and streets, 31%; apartments, 15%; homes, 37%; business, 5%; industry, 6%; and recreation, 6 per cent.

(4) Re-zoning should be along scientific lines after a careful survey of the city and of the trends in other cities of similar character; and it should be without property owners' selfish and half-baked notions. The average property owner will not devote enough time to the problem to understand it and support re-zoning in his own interest, especially in areas now over-zoned for business use.

(5) Re-zoning should be planned so that each area which shows definite trends can develop in conformity with that trend, carefully considering the relation to abutting districts of higher or lower classification, and giving special attention to the developments permitted along common boundary lines.

(6) A metropolitan committee is recommended consisting of property owners, realtors, architects, builders, traffic men, financiers, attorneys, physicians, health authorities, officials of street railway and bus companies, planning agencies, and engineers. Planners should profit by former zoning; present their findings to the City Council and have them enacted into a law with "teeth" in it; make re-zoning conditions non-political.

(7) The major objectives of zoning are born of economic necessity. Zoning is an effective stabilizing factor in real estate and is an important contribution

to enhancement of all civic values. It is a needed preventive and a civic insurance against blight and slum conditions.

(8) A practical supply-and-demand analysis (covering both the present and potential need for residential, business, and industrial uses, based upon up-to-date, accurate, detailed information, and upon comprehensive planning considerations) is the proper formula for re-zoning. This will include much more drastic limitations on the size of residential buildings, as well as on the area devoted to business.

(9) The main problem, in addition to reducing business zones, is to reduce vast areas zoned for large apartment houses, but built up with single dwellings, "duplexes," and flats, to zones protecting existing uses. The principal arguments in favor of such re-zoning are: Additional protection to home districts; stabilization of property values and community development; prevention of blight caused by evacuation of home owners to newer protected areas when apartment houses intrude; and prevention of new assessments to provide additional public utilities to replace those overtaxed by the increased population brought in by the intruding apartment houses.

(10) Re-zoning should be based on a land-use survey of the present built-up areas, and upon an estimate of the future trend of growth of undeveloped areas and their suitability for different classes of uses.

CONCLUSIONS

1.—The evidence is quite convincing that cities, particularly the larger cities, must be re-zoned if urban area uses are to be proportioned correctly and located in advance of any further city development.

2.—Zoning plans must be recast in many respects to provide an equitable and sound basis for tax valuation.

3.—Land-use surveys show conclusively that absorption of urban areas occurs in accordance with definite factors, which can be applied with reasonable accuracy in apportioning city areas for various uses.

4.—Property now static because of improper zoning must be cleared of its fictitious use as a prerequisite for its development to its highest and best use.

5.—The method of re-zoning must first be tested against a land-use survey; then an intelligent analysis of the results of the survey must be made to determine present land use and trends; third, the factors of use absorption must be determined, based on this survey, but taking into consideration surveys made in other cities of similar character; and, finally, these factors must be applied intelligently not only to present developed areas, but also in the allocation of use areas for the future absorption of vacant properties in accordance with anticipated growth.

6.—Upon completion of the fact-finding survey and the recasting of use, an official plan should then be prepared by an official planning body.

7.—A strong citizens' council should be formed to serve as an advisory group to the planning body and to throw the weight of all civic organizations back of the re-zoning plan—a body that should be free politically, and frank, firm, and thorough in its job of informing the people in regard to the need for, and benefits of, re-zoning.

8.—This council should co-ordinate its efforts and those of the planning body with the tax assessor's office in the preparation of a plan providing an equitable valuation of property for taxation purposes, developing information as to the ultimate beneficial effects that will result from having property revitalized and put in line for developing into its highest and best use.

9.—It should be the policy of the city to seek approval of re-zoning on the basis of an official zoning plan based upon a scientific analysis of land-use information. Such a plan should be used in the determination of use absorption for the present and future; and planners should develop a direct official method of putting it into operation through the instrumentality of the citizens' council, which should strive in an intelligent and aggressive manner to remove the blight of present fictitious zoning and secure the adoption of a re-zoning plan for equitable taxation.

10.—A vital factor in the re-zoning and rehabilitation of blighted areas is the correction of the conditions that are causing manufacturing and industry to decentralize. It should be the purpose of the citizens' council to re-zone and to re-value blighted district property for taxation in a manner that will retain, as well as attract, additional diversified manufacturing, a most essential requirement if employment is to be found that will make it possible for the residents in these areas to live in low-cost housing.

11.—The citizens' council should adopt a policy that will embrace the paternalistic method of rehabilitating blighted areas, because it will find application in large areas of the lowest income groups. In addition to the plan of Federal loans and grants to municipalities in the present policy of decentralizing the housing administration, consideration should be given to the alternate method of permitting property owners to assemble their property under some form of trustee plan that will permit the development of large areas of low-cost housing with the aid of Government loans and grants. The first method places the ownership and administration of a low-cost housing project perpetually with the governmental body; the second method would make possible the development of much larger areas for low-cost housing, and would place the ownership and administration in the hands of the property owners themselves.

12.—The policy adopted by the citizens' council should also include the non-paternalistic method, because this will enable property owners to pool their interest in some form of trusteeship that can operate as a limited profit housing agency. Both the paternalistic and the non-paternalistic methods of low-cost housing are necessary for the rehabilitation of blighted districts. The non-paternalistic method should include some appropriate plan that will permit the property owners themselves to become a factor in the rehousing process by pooling their interests into some form of trusteeship that will greatly amplify the scope of rehabilitation and obviate the transfer of too much real estate to the governmental authority.

Finally, with the following factors assured: (1) The stabilization of property use in blighted areas; (2) the correction of factors that are now operating to decentralize manufacturing and industry; (3) the development of low-cost housing projects by any of the methods proposed; and (4) the full co-operation of the city in the matter of utilities and the creation of badly needed park areas in locations that will serve as buffers between manufacturing property and residential property—it is a foregone conclusion that private capital will be attracted on a large scale to the construction of housing for the higher income groups. They will be especially attracted along the boulevards and major and minor streets crossing the blighted territory, particularly if proper attention is given to the design and construction of these thoroughfares, a matter that will be feasible in the rehabilitation process.

DISCUSSION

ROBERT D. KOHN,[4] ESQ. (by letter).—In 1936, the writer came to the realization that no adequate change had been made in the zoning laws applying to the City of New York, N. Y., especially as to the density of use, although a building boom of a kind seemed to be on its way. It has not actually eventuated but much construction of a purely speculative nature was done in 1937. Such building, which planners have feared and tried to prevent, is going on with the same density that was permitted before.

The fact is that the very basis of zoning in New York City is absurd. That is, the absurdity of any scheme based on a scarcity of price placed on land when no scarcity exists. Before planners can get started on any worth while change they must make the difference between price and real value known to the public and faced by the real estate owner. For the difference is colossal. The high price is based in some measure on this very unrealistic zoning which has been accepted. The Housing Authority of New York found that districts zoned for residential purposes in New York City, if built up to the extent permitted by the zoning law, would accommodate 77 million people, and that areas provided for business and manufacturing would accommodate, if built up to the extent they were permitted by the existing zoning law, 340 million people, or, all the people in North America and South America combined.

Whenever a piece of property in a blighted area is purchased for housing purposes, the price the buyer must pay is based on the assumption that the land might be used for some purpose that the zoning law permits and to the limit permitted by the zoning law. Even if the idea with regard to trustee plans for combining properties in blighted areas were adopted they will not work as long as either the trustees have to base their plan on prices that have no relation to real values—earning values—or if the co-operative body is the State, the city, or the nation, and is forced to pay those prices. Another matter to which Mr. Young referred suggests that if the principle of earning value for land were really established, instead of scarcity price, the city would be bankrupt within one year because its tax base would disappear.

Those who are interested in this subject must begin by educating the public to the fact that there is this colossal spread between price and value; that owners can never really get such prices for their land, absurdly based on the idea that all the people in North America and South America will be working in an area such as the New York district, or the Chicago district. Planners will never accomplish anything with housing or better city planning until they realize that the entire present structure of real estate prices is built on a false basis.

MYRON D. DOWNS,[5] ESQ. (by letter).—Why is there a need for re-zoning cities zoned ten to twenty years ago? Most of the older ordinances were prepared by capable consultants, although many of them were written by city solicitors or city engineers' assistants under the direction of city councils seeking an economical method of satisfying a persistent group of citizens. Unfortunately, many consultants and the non-professional planners did not consider it essential to study other elements of the city plan prior to the recommendation of a zone plan. Too many zone plans already prepared and adopted, constitute merely maps of existing uses, no effort having been made to proportion the several types of use scientifically. It is well to bear in mind that the United States Supreme Court, in its decision in favor of the Village of Euclid, Ohio, in 1926, found zoning a constitutional exercise of the police power when based on comprehensive planning. It is not to be inferred carelessly that any map of an urban area, divided into three or four types of use districts, will withstand successfully the test of time, either in the Courts or as a medium for furthering the elements of a comprehensive and complete city plan, which should be the planner's test of a good zone plan. It would seem that the greatest need for re-zoning urban areas exists by reason of failure to plan first.

---

[4] Archt., New York, N. Y.

[5] Secy., Cincinnati City Planning Comm., Cincinnati, Ohio.

Mr. Young states (see heading "Need for Zoning: Why Zone") that "city planners have come to sense the great social need of transforming the physical structure of urban areas." It is to be hoped that his observations are correct. If so, the larger cities which, twenty years ago, followed New York's leadership in zoning, will again play "follow the leader" and provide workable public agencies in the form of public housing authorities to do the work. Much of the practical difficulty involved in the operation of housing projects by the Federal Government had its beginning in the form of bad land sub-division practice and the speculative rather than investment campaigns to "own your own home."

The author properly emphasizes the need of a strong administrative branch of government if good zoning is to succeed. Liberal or inadequate enforcement is very quickly resorted to, if a poor piece of zoning has been done by the planner, or if municipal officials have not provided for adequate planning as a foundation upon which to base the zone plan. Many a community has turned to the supposed economy of charging the assistant sewerage engineer and the bridge engineer's draftsman with the task of supplying the local planning commission with a zone plan during idle winter months. Naturally, the product of their efforts is comparable with that of a planning engineer, suddenly and without special technical training, assigned to the task of designing a sewage treatment plant for a community of unknown population, or detailing the shop drawings for a bridge of unknown length, width, and loading. Use of the resulting structures, in either case, is perilous.

Advances in the quality of public planning must be gradual and ideals must be compromised. Cities with too few use districts for proper transition, can amend the use district map. In 1932 the City of Cincinnati increased its use districts from eight to ten, providing thereby an intermediate residence zone between the one-family house district and the three-story, multiple-family building district, and a new business zone restricted to local services and goods establishments, with height limitations in keeping with those of surrounding residential areas.

There is still room for improvement, in most large communities, in the public control of population density. Height, area, and bulk regulations are of relatively little assistance in regulating population to the extent that school buildings and pavements can be built with any degree of certainty that the estimated capacity will not prove inadequate long before the bonds issued for the improvement are retired. There are few large cities which do not have some area congested with a density of more than 100 persons per net acre of land, and, what is more serious, they have no legal control of density in other areas, commercial or residential. Both Chicago and Cincinnati have certain areas with densities in excess of 120 persons per acre.

High buildings always present a difficult problem to the planner, in so far as the regulation of bulk is concerned. Cincinnati has improved the bulk regulation of the central business district approximately 25% by the recent amendment (1932). However, as emphasized in 1936 by Mr. Harold S. Buttenheim,[6] the provisions are still most liberal. (The total cubical contents above the established grade must not exceed the contents of a prism having a base equal to the area of the lot and a height equal to two and one-half times the width of the street—maximum, 250 ft.)

Good zoning, and the ability to place it on the ordinance books of any city, can only result from a good quality and an ample amount of technical work by competent planners supported by community endorsement of a planning commission of proved integrity.

HARLAND BARTHOLOMEW,[7] M. AM. SOC. C. E. (by letter).—A most convincing case for the re-zoning of urban areas is presented in this paper. Surely, no one who has studied this problem in large American cities can deny its necessity. Apparently, there is now a wide realization of this need, which is indicated by the large number of cities which express themselves in favor of re-zoning in answer to Mr. Young's inquiry.

Cities will be re-zoned to best advantage only when the plan is based upon an accurate knowledge of the total land in urban use for various purposes and the annual rate of absorption. It is interesting to note how closely Mr. Young's data for the total area of land used for urban purposes in Chicago and certain suburban areas corresponds with similar values for about sixteen self-contained cities cited by the writer.[8] Had Mr. Young been able to secure data for all land in urban use in all the incorporated and unincorporated areas in the Metropolitan District of Chicago, there is no doubt but that the data would have corresponded even more closely with the average in other cities. There are well-defined laws of land use which, when thoroughly understood, will make possible far more scientific zoning practices.

In 1937, the St. Louis (Mo.) Regional Planning Commission made a land-use survey of the entire 840 sq miles within the St. Louis Metropolitan District, with the aid of the Federal Emergency Relief Administration (FERA) and the Works Progress Administration (WPA). The percentage of land used for various purposes in this Metropolitan District (which is really nothing more than a very large self-contained city) corresponds very closely with the average percentage used for various purposes in the sixteen self-contained cities (see Table 6).

[7] (Harland Bartholomew & Associates), St. Louis, Mo.

[8] "Urban Land Uses," by Harland Bartholomew, Harvard Univ. Press, 1932.

TABLE 6.—LAND USED FOR VARIOUS PURPOSES; PERCENTAGES

Purpose	Average of sixteen cities*	St. Louis Metropolitan District	City of St. Louis
Single-family dwellings	36.10	29.58	20.4
Two-family dwellings	2.10		7.7
Multiple family dwellings	1.09	2.38	7.5
Commercial areas	2.38	4.27	5.3
Industrial areas	10.79	17.60	14.5
Streets	33.60	25.57	26.2
Parks and playgrounds	6.33	4.38	8.0
Public and semi-public	7.61	16.22	10.4
Total	100.00	100.00	100.00

* "Urban Land Uses," by Harland Bartholomew.

The importance of including all the area in urban land-use surveys, regardless of municipal boundaries, is revealed by Table 6. Although the percentages of land used for various purposes in the St. Louis Metropolitan District correspond fairly closely with those of the sixteen self-contained cities, it will be noted that those for St. Louis (which is only part of a self-contained city) show certain marked variations from the normal averages. Re-zoning of partial urban areas should be undertaken only after a full knowledge of total urban land-use characteristics based on comprehensive surveys.

Most city planners will agree with all Mr. Young's fourteen conclusions. It is particularly interesting to note that he concludes that both public and private enterprise will have to unite in the rebuilding of blighted districts—a conclusion that should be closely noted by the extremists who advocate one or the other of these methods of approach as the only possible means of solving these problems.

Mr. Young advocates the creation of a strong citizens' council to promote the re-zoning plan which has been prepared as the result of the land-use survey. With this the writer is in full sympathy, but the success of this council depends upon many factors. The desires of a small but influential group of property owners have caused bad distortions in original zoning ordinances. These same speculative interests have been responsible for many unwarranted changes in zoning ordinances after their adoption in many cities. What assurance is there that any sound re-zoning ordinance adopted as the result of the initiative of a strong citizens' council will not gradually be broken down by these same speculative interests? Some kind of a permanent agency is needed to insure that all zoning is soundly conceived and wisely maintained. It is for this reason that the writer advocates one step farther than Mr. Young in his approach to this problem.

A real objective view of the present American city reveals it to be divided into three different types of residential areas: (1) Slums; (2) blighted districts; (3) new sub-divisions and suburban areas.

The actual slum areas are found generally in the oldest residential districts. They are relatively small in size, constituting probably not more than 5% of the total land in urban use. There is nothing that can be done about them except tear them down completely and rebuild them upon a totally new plan. The new sub-divisions and suburban areas are also relatively small in size, constituting perhaps not more than 20% of the total land in urban use. There is no immediate problem in these new areas other than that of protecting and preserving their present character. This is fairly well provided for by deed restrictions and by zoning regulations. The greatest success with zoning has been in preserving the character of new development.

Between the slums and the new suburban developments lies a vast area of residential development in various stages of decay. These are the blighted districts. They are all potential slums. Probably the most severe indictment that could be brought against the American city of to-day is the failure to give adequate protection to residential areas, from which more taxes are collected than from all other urban land uses, commerce and industry included. Residential development, particularly of the one-family and two-family types, once developed in an American city, soon starts either a gradual or a rapid process of depreciation. These large blighted districts cannot and need not be rebuilt. They are too large and the individual buildings within them are not yet obsolete. The problem then is one of rehabilitation rather than reconstruction. Sound rehabilitation involves the development of constructive urban land policies heretofore almost completely absent in American cities.

Thus, there are three different problems within the urban residential area: (1) Reconstruction of slums; (2) rehabilitation of blighted districts; and (3) protection for new suburban development. Zoning, in itself, or re-zoning, will not accomplish either of these three objectives. It will do very much to facilitate each of these objectives and, in fact, is indispensable to each of them. Zoning, or re-zoning, however, is merely one phase of urban land policy. To accomplish the desired objectives in all three areas involves a long-time program and continuous study of relatively small unit areas of land within each of the three broad areas. The writer, therefore, favors the division of all the residential areas, slums, blighted districts, and newly developed areas, into a comprehensive plan of neighborhood units, and the formation within each unit of a citizens' organization for permanent study and planning, as well as for concerted action in all matters pertaining to the welfare of the neighborhood unit which it represents.

Stability of home ownership and satisfactory living conditions have been destroyed by uncontrolled speculation in urban real estate. One can never establish stability and desirable living conditions without control of real estate, which is consistent with normal land use. Where there is a city plan commission capable of determining broad principles of land policy, and a well organized neighborhood unit in each part of the residential area, planners can soon determine what is the proper zoning and policy of land development within each neighborhood; and when the citizens of each neighborhood realize and understand what the zoning and land policy should be, they will have a far better chance of adopting, enforcing, and maintaining appropriate zoning and other parts of a sound land policy and program.

This comment, with respect to the establishment of permanent agencies in the form of neighborhood units and neighborhood unit organizations in the interest of slum clearance, rehabilitation of blighted districts, and protection of new residential areas, as previously stated, is merely supplementary to, and in no sense believed to conflict with, Mr. Young's recommendations. The writer is in full sympathy with his recommendations, and he should be congratulated upon the preparation of so thorough and so constructive a paper.

BENJAMIN SALTZMAN,[9] ASSOC. M. AM. SOC. C. E. (by letter).—The increasingly large number of municipalities which have adopted ordinances regulating the use to which land and buildings may be put, and limiting the height and bulk of buildings, is evidence that the benefits of a sound zoning system have been recognized everywhere. The private restrictions that constituted the sole regulations prior to zoning, were haphazard and sporadic, covered only a small area, and were formulated and often distorted by the developer to secure him a maximum financial return. These private restrictions were inflexible and, under changing conditions, frequently impeded the logical growth of the neighborhood, thereby making application to the Courts necessary for their removal. As cities became larger the need for city-wide regulation became more and more essential. It was apparent that city planning and zoning are inextricably intertwined. It was difficult for a community to plan street and block layout, park and recreational facilities, water supply and sewerage systems, transit and transportation systems, port and terminal facilities, and to locate schools and hospitals when the control of the city extended only over city-owned property, and when private property, covering about two-thirds of the city's area, was permitted to develop without any control, although the manner in which private property was developed strongly influenced the direction of city planning. No plan for the development of public facilities can be complete or effective which is not based upon a comprehensive plan of control of building development on private property.

It is comparatively simple to map a proposed city along logical zoning lines. It is extremely difficult to zone land which has developed haphazardly, especially in a large city created by combining many smaller municipalities, each of which developed independently. The average zoning ordinance, as first enacted, represents a series of compromises between the city planner working along established principles of zoning and the real estate interests desirous of diverting the ordinance to those directions which might enhance the value of their property, which explains the unusually high percentage of land zoned for industry.

Almost every zoning ordinance contains "congenital" defects which prevent the fullest realization of the benefits of zoning and which contribute toward the creation of blighted areas. As time elapses the defects become glaringly apparent and real estate interests become reconciled to the idea that re-zoning is necessary. To determine the nature and the extent of re-zoning requires an examination of the ordinance, a study of what it sought to achieve, where it failed of achievement, and the factors contributing to that failure. All the symptoms must be studied, and a diagnosis made before any remedy can be prescribed.

---

[9] Asst. Engr., Dept. of Buildings, Brooklyn, N. Y.

Zoning is designed primarily to reduce congestion, provide adequate light and air, keep obnoxious uses out of residential areas, lighten the burdens of traffic regulation and fire protection, ease the strain on transportation systems, reclaim blighted areas, and finally, to stabilize real estate values. Haphazard building tends to reduce taxable values, as entire districts may become depreciated, while orderly development aids in the conservation of property values.

An area that has been properly zoned will not become blighted. A residential area that has been protected against invasion by industry by a buffer zone devoted to local business use, will retain its essential character for many years. An area devoted to one-family or two-family dwellings must be protected from the congestion caused by the erection of multi-family dwellings. In New York City, the ordinance needs revision in this respect, as the only restrictions designed to keep the multi-family dwelling out of the single-family area are limitations as to height and bulk, which are, more and more frequently, legally and successfully evaded. Where such areas, even if well shielded, do decay and become blighted through obsolescence and gradual occupation by lower-income families, the remedy is not to re-zone so as to permit business or industry to enter, but rather to re-build, either with private capital or Government housing, or both.

Most blighted areas have either been improperly zoned in the first instance or have been destroyed by an invading industry which later departed, leaving the empty shells of buildings as a reminder of their existence. These are the areas to reclaim. Instead of encouraging the development of out-lying districts, which induces abandonment of the old, and removal to the new, by extension of rapid transit facilities and by the creation of other desirable features, this emphasis should be placed upon the redemption of the old. It is illogical as well as uneconomical to permit an area provided with schools, streets, fire-fighting equipment, sewers, water supply lines, and transportation facilities, in fine geographical locations, to decay and become more and more uninhabitable, with real estate values wasting away, and proceed to duplicate all this expensive development in some outlying part of the city.

Decentralization of industry may become a cause of blight, but it may also be made to contribute to progress rather than to retrogression. If industry could be confined to small areas, each surrounded by local business uses and then by residential area devoted to the homes of the workers, the strain on transportation systems would be eased and street congestion materially reduced. Unquestionably, too much area has been zoned for industrial use; segregation and the reduction of these areas to reasonable limits would fix real estate values and diminish the area subject to blight.

Re-zoning alone, however, is insufficient to correct all the negative factors that contribute to the ineffectiveness of a zoning ordinance. The defects in the ordinance may be noted and noted, and the areas to be devoted to different uses scientifically apportioned, and yet the entire system may break down in the enforcement of the law. The zoning ordinance must be administered honestly and capably to be successful. Political expediency or personal favoritism have no place either in the administration of the law, in the granting of variations, or in the framing of amendments to the ordinance or the maps.

The burden of administration and enforcement is lightened by the requirement of a certificate of occupancy for every new or altered building. The issuance of this certificate is an assurance that the building complies with all the laws applicable thereto, including the zoning ordinance, and occupancy contrary to the terms of the certificate is in violation of the law. The certificate of occupancy is a public record, and any person interested can easily determine the contents of any certificate. Illegal occupancies may be noted and corrected. The department charged with the enforcement of the ordinance should issue the certificate; any other method results in a shifting of responsibilities and bickering between the agency enforcing the law and the one issuing the certificate. In New York City, the Department of Housing and Buildings administers the zoning ordinance, with a Borough Superintendent in charge of each Borough. This Department, or its predecessors in duties, has issued certificates of occupancy since they were first required in 1914. It is only on rare occasions, and then in border-line cases of interpretation of the law, that these certificates have been challenged by any request for revocation.

In New York City the City Planning Commission has the authority to amend the zoning ordinance and the maps; the right to grant variations from the strict requirements of the law, in stipulated conditions, is vested with the Board of Standards and Appeals. Both these bodies act only after public hearing. Variations in interpretations of the zoning law are granted only after thorough investigation and upon a sound legal basis, only where the development along conforming lines would inflict unnecessary hardship or where practical difficulties intervene; and then only under such conditions as will safeguard the character of the neighborhood. Furthermore, the relief granted to an applicant must not inflict any hardship on neighboring property owners. The Courts have consistently upheld the Board in their decisions along these lines.

The full benefits of zoning or re-zoning cannot be secured unless the concomitant problem of the non-conforming use is solved. In any area previously zoned for business or industry and re-zoned for residence use, or in any area previously zoned for industry and re-zoned to permit only small local business use, there will be numerous buildings whose use does not conform to the regulations for the new district. It is the hope of the zoning engineer that eventually obsolescence and natural decay will force the demolition of these structures. Where the Board of Appeals grants indiscriminate variances permitting the modernization or enlargement of such structures, the effectiveness of the ordinance is impaired and the restrictions become valueless. The Board, therefore, at all times, must regard the interests of the community as paramount, and allow variances only where the granting of the appeal is imperative and where denial would be equivalent to confiscation of property. Unless such an attitude is maintained re-zoning is valueless. Honest and capable administration of the ordinance is the keystone of the structure of zoning; without it any zoning or re-zoning is an idle gesture.

G. H. **Herrold**,[10] M. Am. Soc. C. E. (by letter).—Much "water has gone over the dam" since the first zoning ordinance was drawn in 1916. Land has changed hands through the years. Lots have been purchased and many built upon in accordance with existing zoning. Skyscrapers have been constructed, filling stations established, apartments designed and built, new plats recorded, thoroughfares and parkways built, playgrounds and parks acquired; and a new conception of land tenure is under way.

To re-zone a city is quite an "upset" and should be approached cautiously and after much study. The average city in the United States that has grown naturally is divided into four classifications as to residential areas:

(1) There is the well-maintained and established high-class residential district in which properties are occupied by the owners. Each property is a specimen with an atmosphere created by the architecture and landscaping of the site and the culture of the owner;

(2) There is the neglected district lying between this stabilized residential district and the commercial or industrial district—neglected in the sense that no one is looking out for it collectively. The owners have lost faith in their investment and in the district;

(3) There is a completely blighted district or slum; and,

(4) There are the new outlying developments in which people in the stabilized districts are invited and importuned to invest.

The great good of zoning (that is, preserving the *status quo* in older districts and preventing the "mussing up" of new districts) has really been attained in the majority of cities. It is possible that the strengthening of health laws or a better enforcement of these laws in slum, blighted, or neglected districts may prove an aid to zoning. A slum district can be rehabilitated by the simple enforcement of cleanliness and structural safeguards, good municipal maintenance, and the enforcement of requirements for light and air. With this aid city planners may give the district a new lease on life under its present zoning.

All zoning ordinances provide for multiple-family dwellings. A multiple-family dwelling may be a barrack, a tenement building, a "four-plex," or a beautiful apartment building. Some definitions are necessary to segregate these different structures in zoning a city. If an apartment building was no higher than near-by residences and took the same setback; if it had an area of land, say, equivalent to 1 sq ft of open area to each square foot of floor area; if it had no common entranceways, it would be appropriate and acceptable in a residential district where houses are rented, especially if limited to locations, such as those adjoining along the side line of different zoning, facing a different zoning, or facing a park, school grounds, or institutional buildings, etc., the opportunities would be unlimited. An apartment building might be defined as a two and one-half story, multiple-family dwelling in which each apartment has its own individual entrance, etc. A tenement might be defined as a multiple-family dwelling with a central hall used in common by all tenants, etc.

---

[10] Planning Engr., The City Planning Board, St. Paul, Minn.

Mr. Young shows that the great grievance is too much commercial, industrial, and apartment house zoning—a lack of balance in the proportioning of areas of zones and the placing of a value on such mis-zoned areas by the assessor that make it impossible to use it for homes.

In St. Paul, Minn., land and buildings are not assessed according to the zoning, they are assessed according to use—the zoning map being used as a guide. There is some unwarranted commercial strip zoning running through residential districts, but if residences predominate the land is assessed as residential property. This is the only rational method of assessing city property.

The only cure for poor administration, of course, is better administration. Zoning boards made up of a personnel with no planning experience are serious defects. Zoning is a part of the City Plan and can best be administered and interpreted by planning-minded people. In St. Paul, the Board of Zoning created by the Zoning Ordinance is the Zoning Committee (five members) of the City Planning Board; thus planning and zoning are tied together.

Some ordinances simply require the elimination of "strip" business zoning and the substitution of "district" business zoning to bring them into a fairly consistent situation as to proportioning the uses of property. This strip zoning, so common in existing ordinances, was brought about by members of "pressure groups," who either did not know what good zoning was or who wished to discredit zoning.

Some ordinances may be brought into line by provisions for terminating non-conforming uses after a period of years. This is an urgent need. In fact, the cure of the non-conforming evil and the reduction of footage of commercial zoning in residential developments might again carry us along over another 20-yr period.

In St. Paul, the Board of Zoning will recommend to the Council the remodeling of a non-conforming store building in a residence district, which is in distress financially, into a "triplex" or "four-plex" if it will move back to the building line of the homes and present a suitable architectural treatment.

In a city like Chicago, Ill., where changes come so rapidly, the proposed re-zoning based on a land-use survey and a proper proportioning of uses as determined by years of experience, is probably desirable, but a land-use survey must also be properly interpreted and this cannot be done by speculators.

Mr. Young has made a notable contribution to this subject of zoning and his analysis of the situation in Chicago, as well as the information gleaned through his questionnaire of December, 1936 (and which he has made available in his paper), will be of great value to all cities that are studying this matter of zoning.

The logical basis for re-zoning is the existing use of property and the anticipated normal absorption of additional property, not necessarily vacant property. This requires a sound knowledge of the trend of a city's growth. The causes of blight which were operating before zoning ordinances were devised and which were not cured by zoning must be rediscovered. Inadequate street, sewer, and water facilities, and poor maintenance were among the causes of blight. These defects must not be confused with alleged poor zoning. Suitable buffering must be considered. There must be a natural stepping up of uses between the district of no restrictions (industrial) and the district of highest restrictions (residence). The use of parkways for buffering industrial districts is probably one of the best.

HUGH E. YOUNG,[11] M. AM. SOC. C. E. (by letter).—Data from seventy-five American cities with populations of 50 000 and more were contained in the paper. This material indicates that many people interested in the municipal problems of these cities are well aware of the need for re-zoning most of the communities. Several basic reasons were given why such a need exists. One was the failure of those who prepared the zoning ordinances to realize that zoning is fundamentally an element of city planning because it is the process which co-ordinates the social, economic, and physical structure of urban areas.

As Mr. Downs states, many zoning plans are merely maps of existing uses, and show no evidence of any attempt to co-ordinate zoning with city planning, or even to proportion the urban area between the various uses in an orderly or scientific manner. Failure to plan properly first, or to co-ordinate zoning with existing city plans, is perhaps one of the basic reasons why re-zoning is now necessary in so many large American cities, although it is not so vital in smaller communities.

Another reason was the illogical and inequitable allocation of land as between various uses, combined with improper distribution of the areas devoted to specific uses. As stated by Mr. Bartholomew, improper proportioning of land among the various uses is indicated by the fact that many cities have zoned an extensive area of land for one use or another that is unjustifiable in the light of well-known factors as to the area that is actually required in terms of acres per one hundred persons, and as to the annual rate of land absorption. Improper distribution (Mr. Bartholomew further states) is shown by the failure of many zoning ordinances to provide residential areas in appropriate relationship to places of work and business.

Mr. Kohn emphasizes a further reason outlined in the paper; namely, that much zoning is based on an incorrect assumption as to what constitutes the highest and best use of a given area, which, in turn, results in unduly high land values, or price as Mr. Kohn calls it. He points out that many zoning ordinances provide for a use in a given area that is speculative rather than factual, and for a density of use so intense as to make the assumed value of the land, if devoted to that use, far greater than its real value, if devoted to its genuine best use. Mr. Kohn believes that not only zoning, but city planning and housing progress as well, are largely dependent upon making the public and the real estate owner realize the difference between price based upon unrealistic zoning and real value based upon appropriate land use.

The paper advocated a real property inventory and land-use survey as the initial step toward re-zoning. The purpose of the survey is to show existing patterns of land use, areas of blight, population changes and other factors which together make re-zoning necessary. Mr. Bartholomew stresses the point that cities will be re-zoned to best advantage only when the re-zoning plan is based upon an accurate knowledge of the total land in urban use for various purposes and upon the annual rate of land absorption. He states that well-defined laws of land use, when thoroughly understood, will make possible far more scientific zoning practices than those of the past, and illustrates his point by giving the percentages of land used for various purposes (see Table 6): (1) As the average of sixteen self-contained cities; (2) in the St. Louis Metropolitan District; and (3) in the City of St. Louis alone. Table 6 indicates the importance of including all the area in urban land-use surveys, regardless of municipal boundaries, because the percentages for the City of St. Louis alone show certain marked variations from the normal averages.

---

[11] Chf. Engr., Chicago Plan Comm., Chicago, Ill.

A considerable part of the paper was devoted to the administration of a zoning ordinance and means for maintaining the integrity of the ordinance, listing some of the bad effects of allowing improper variations therefrom. The writer showed that no zoning ordinance will be effective unless its administration is in strong hands, free from political domination; and suggested that the essential need was for a strong public body, such as a plan commission, to lend support to the Zoning Board of Appeals. Furthermore, he showed that a certificate of occupancy is most important for the proper functioning of the zoning ordinance, but that such certificate should not be issued by the same department that is charged with its enforcement.

Mr. Herrold asserts that zoning is a part of city planning and can best be interpreted and administered by planning-minded people. He adds that in St. Paul the Zoning Board created by ordinance is composed of the five members of the Zoning Committee of the City Planning Board of St. Paul.

Mr. Saltzman states that re-zoning, alone, is not sufficient to correct all the negative factors that contribute to the ineffectiveness of a zoning ordinance. He states further that, even with a good re-zoning plan, the ordinance must be administered honestly and capably if it is to be successful. Certainly, honest and capable administration of the ordinance is the keystone of the structure of zoning; without it any zoning or re-zoning activity is an idle gesture.

Mr. Saltzman states that the burden of administration and enforcement of the zoning ordinance will be lightened by the requirement of a certificate of occupancy for every new or altered building. This is because the issuance of this certificate is an assurance that the building complies with all the laws applicable thereto, including the zoning ordinance, and occupancy contrary to the terms of the certificate is in violation of the law. Certificates are a public record, so that illegal occupancies may be noted and corrected. Mr. Saltzman, however, is firmly of the opinion that the department charged with the enforcement of the ordinance should issue the certificate, because any other method would result in a shifting of responsibility, and bickering between the agency enforcing the law and the one issuing the certificate.

Mr. Downs emphasizes likewise the need of a strong administrative branch of government if good zoning is to succeed. Mr. Bartholomew advocates an even more advanced step than the writer's organization of a strong citizen's committee in order to preserve the integrity of a re-zoning ordinance. He suggests the establishment of permanent agencies in the form of neighborhood unit organizations in the interest of slum clearance, blighted district rehabilitation, and the protection of ideal residential areas. His point is that uncontrolled speculation in urban real estate has destroyed the stability and desirability of home ownership; hence it is essential to control real estate in a manner consistent with normal land use. Mr. Bartholomew, therefore, favors having the plan commission determine the broad principles of land policy, and having the citizen's committee as recommended; but in addition he recommends the establishment of well-organized neighborhood units to assist in adopting, enforcing, and maintaining appropriate zoning policies and a sound land program.

One defect in present zoning practice to which the writer called attention was the lack of adequate "buffer" areas between various uses. He stated that zoning practice is still in a crude stage with respect to the "tapering off" process—that is, the transition from a higher to a lower use, especially by means of park strips between residential sections and those used for other purposes.

Mr. Herrold agrees that suitable buffering must be considered, and that there must be a natural stepping up of uses from the less restricted districts to those which are more highly restricted. He gives it as his opinion that the use of parkways for buffering industrial districts is probably one of the best methods.

The paper demonstrated the detrimental effect of zoning variations and the problem of non-conforming use. Mr. Saltzman states that the full benefits of zoning or re-zoning cannot be secured unless the concomitant problem of non-conforming use is solved. He calls attention to the fact that any re-zoning will result in there being, in most districts, many buildings whose use does not conform to the regulations for the new district. Although obsolescence and natural decay will force the eventual demolition of some of these structures, this process will be hampered, the effectiveness of the ordinance will be impaired and the new restrictions will be valueless if the authorities allow indiscriminate variances that permit of the modernization or enlargement of such structures.

It is naturally gratifying to find so complete an agreement on the part of all those who participated in the discussion with respect to the principles set forth in the paper. One point made, however, was not discussed by any one. It is a matter of such basic importance that it should, once again, be called to the attention of the reader. That is the need, when re-zoning, to provide for reciprocal protection for all the various use districts.

Every one is aware of the need for protecting residential areas against the incursion of commerce and industry, but it is equally important, for example, to protect manufacturing areas against incompatible commercial uses, and particularly against the restrictions which often result from the presence of near-by residential use—restrictions which work a hardship upon manufacturing operations of the so-called "nuisance" type but which are, nevertheless, an important element in the city's business and financial life.

Much of the paper was devoted to the subject of blighted areas and the possibility of their redemption. Re-zoning was suggested as the first step, apportioning city areas for various uses in accordance with definite factors of land-use absorption as developed by a land-use survey, because improper zoning is a blight in itself in that it specifies a use and volume that can never be attained.

The second suggested step was the preparation of an official plan by an official planning body, and the establishment of a strong citizen's group to advise the plan commission with respect to zoning, and to throw the weight of all local civic organizations back of the re-zoning plan.

The writer took the position that both the paternalistic (public) and the non-paternalistic (private) methods of providing adequate housing facilities were necessary elements in the rehabilitation of blighted districts. The paternalistic method is that of providing low-cost housing for the lowest income groups by governmental agencies and governmental financing. The non-paternalistic method, enabling groups of property owners to redeem a neighborhood as a private undertaking, would seem to have taken hold on the public mind in recent months. State legislation is pending in Illinois, and has been suggested elsewhere throughout the nation, looking toward the establishment of "Public Service Building Corporations" with specified powers of land condemnation under the right of eminent domain. This latter feature is designed to overcome what has been heretofore the greatest obstacle to the rehabilitation of blighted areas as a private enterprise.

The public service building corporation plan, originated in Chicago as a means of interesting private capital in slum clearance housing projects, is now (1939) being considered in New York City. The Merchants Association of that city has also suggested that additional legislation be enacted which will permit the formation of local district improvement corporations. In this plan the equity would be represented principally by shares of stock given by the corporation to present owners and mortgagees in exchange for their claims on the property and its present and potential earning power.

For both the public service building corporation and the local district improvement corporation, powers of eminent domain would be granted upon proof that they were necessary to bring minority groups or their property within the scope of an approved large-scale rehabilitation plan.

NOTE.—Presented at the meeting of the Society and at the Joint Meeting of the Power and Engineering-Economics and Finance Divisions, Pittsburgh, Pa., October 14, 1936. Publication has been made possible by the financial co-operation of the Power Division. This Symposium was published in December, 1937, *Proceedings*.

PROGRESS IN THE GENERATION OF ENERGY BY HEAT ENGINES

BY GEO. A. ORROK,[1] M. AM. SOC. C. E.

SYNOPSIS

The writer gives estimates of the total of power-producing machinery used in the United States as of 1936 and discusses hours of use and kilowatt-hours of work done annually, showing the contrast between 1880 and 1936. The size and type of units with the average economies of various types of machinery are given. The influences of high pressure and vacuum and high temperature are discussed with prediction of economies now in sight. Thermal economy and commercial economy are discussed as well as the cost of installations over the period. Tables are given for the cost of steam power.

The internal combustion engine, Otto, Diesel, and solid injection cycles, are considered and the paper ends with a review of possibilities of other cycles and other mediums of heat supply. The conclusion is that steam will be the most used medium of power generation for the near future.

In 1896 the late Robert Henry Thurston, M. Am. Soc. C. E., surveyed the field of power production and collected data on the increasing use of steam power during the Nineteenth Century.[2] It is interesting to note that his figures for 1896 show only 17 000 000 hp of power-producing machinery in the United States, divided as follows: Locomotive, 11 000 000 hp; marine, 2 000 000 hp; and stationary, 4 000 000 hp. He plotted his figures in a curve, and commented on the trends of the possible tremendous increase in power output which has since taken place.

In 1909 Henry Adams, some time Professor of History at Harvard College, wrote his essay on the Phase Rule which was published posthumously in 1919 as "The Degradation of Democratic Dogma." In this essay Professor Adams speculated as to the great increase in the use of power in the world and tried to apply the second law of thermodynamics to the power situation. His curves show the same characteristics as those of Thurston, but with the well-known Adams pessimism, he carried the curve to its logical conclusion, forgetting the law of diminishing returns with which he was without doubt much more familiar than with the second law of thermodynamics.

Among the authorities who have since contributed to power statistics both in the United States and in other countries may be mentioned, D. B. Rushmore,[3] M. Am. Soc. C. E., F. R. Low,[4] and Professor Thomas T. Reed.[5]

[4] Presidential Address, A. S. M. E., Vol. 46, 1924, p. 1535.

[5] *Mechanical Engineering*, May, 1926.

In 1930, the writer brought these figures up to date[6] (for the United States only), and more recently the increases from that year to June, 1936, were shown by Dean A. A. Potter in his paper for the National Resources Committee.[7]

According to Dean Potter, the total horse-power of prime movers in the United States in June, 1936, was divided as follows:

	Horse-Power
Electric central stations	44 670 000
Industrial power plants	20 133 000
Electric railway plants	2 500 000
Isolated non-industrial plants	1 500 000
Mines and quarries	2 750 000
Agricultural prime movers	72 763 000
Automotive	965 000 000
Airplanes	3 500 000
Locomotives	88 000 000
Marine	30 000 000
Total	1 230 816 000

It is to be noted that the transportation services accounted for more than three-quarters of the power-generating machinery shown in Thurston's figures in 1896, while Potter in 1936 credits more than 91% to transportation—thus justifying Kipling's statement that "transportation is civilization." Of the 91% credited to transportation, about 8% use steam as the heat medium, and 92% use oil or gas in internal combustion engines. Of the stationary power plants (except those credited to transportation), Dean Potter schedules 56 684 000 hp in steam plants, 16 075 000 hp in water-power plants, and about 2 000 000 hp in oil and gas engine plants. Roughly, then, the stationary plant installation can be classified as 20% water power and 80% steam power.

When it comes to the actual horse-power-hours, kilowatt-hours, or work done, the figures are a little uncertain. However, it is probable that the 1935 output of the steam and water-power plants alone was not far from the equivalent of 142 000 000 000 kw-hr, of which more than 100 000 000 000 kw-hr was generated by steam. The average per capita use of power, central station plus industrial, is thus on the order of 1 115 kw-hr per yr. The equivalent kilowatt-hours of transportation power, locomotive plus automotive, is estimated conservatively at a somewhat larger amount than the stationary power, say, 150 000 000 000 kw-hr—hence, the total per capita use may be taken as the equivalent of 2 300 kw-hr per yr.

Whether the curve of prime-mover capacity is plotted from 1 800 (Thurston's curve) or from 1 500 (Adams' curve), the ascending segment is steep, and a 10-yr moving average smoothes out sufficiently the cyclic irregularities. (The curve of equivalent kilowatt-hours use follows practically the same law, the growth in use factor being very slow.) There is as yet little sign of the saturation that is evident in population curves, but this may appear in the future, particularly as the trend is toward a stationary population in the next twenty years.

[6] Rept. on the "Status and Progress in the Art of Power Engineering," *Proceedings*, Am. Soc. C. E., March, 1930, Papers and Discussions, p. 437.

[7] Rept. of National Resources Committee, 1937.

The remainder of this paper omits from consideration the power used for transportation and that part of the stationary power that is generated by water, and is concerned solely with the stationary power-plant installation of 58 700 000 hp of heat engines. In most of this installation (56 680 000 hp), steam is the heat transfer medium.

The average annual use of this installation is about 1 730 hr, therefore, the total annual output of the steam plants is roughly 98 000 000 000 kw-hr. The central station output of 55 000 000 000 kw-hr is generated at an expenditure of about 1.45 lb of coal per kw-hr, while the industrial output of 43 000 000 000 kw-hr requires not far from 3 lb per kw-hr. The average use for both classes of plants is 2.13 lb per kw-hr, or the equivalent of 104 000 000 tons of coal per yr, roughly, 20% to 25% of the total annual coal output of the country.

In 1882, the late Thomas A. Edison considered 10 lb of coal per kw-hr a very good record for the first central station. F. R. Low, in 1891, reported to the National Electric Light Association that only one central station reported an economy as low as 4 lb of coal per kw-hr. His actual words were "250 watts per lb of coal." In 1936 the central station, at Port Washington, Wis., was consistently operated at an economy of 0.86 lb of 13 000 Btu coal per kw-hr—an over-all thermal efficiency of 30.6 per cent. In 1880, the late William Cawthorne Unwin, Hon. M. Am. Soc. C. E., the English authority on steam generation and use, considered 12 lb of Welsh coal per ihp-hr an average record in industrial establishments. This is equivalent of 16 lb per kw-hr. In 1936, industry was averaging about 3 lb per kw-hr of poorer coal and A. G. Christie[8] quotes a figure of 0.93 lb for one large modern industrial plant.

In 1880, in England, Unwin tested a Lancashire boiler and found the efficiency to be a little more than 80 per cent. Two years later, in the United States, J. C. Hoadley tested a return tubular boiler that gave 83% to 85% efficiency with a small air heater and about 79% without the heater. Power engineers have re-introduced the feed-water heater (which Edison used in the first of all central stations), the superheater, and the air heater, or economizer, making them a part of the modern boiler. They have added water-cooled furnaces, invented more than 100 yr ago, but not coming into general use until 1924. They have taken the stoker, invented about 1861, and improved it until it is nearly automatic, and they have perfected the burning of pulverized fuel. Even such fuels as lignite, or brown coal, containing 65% of water, are fired efficiently on a stepped grate. Oil wastes and acid sludges are also burned with high efficiency. Boiler tests currently show efficiencies of between 82% and 92%, and whenever it should become commercially feasible, these values can be exceeded. Year-round boiler-house efficiencies of from 78% to 88% are regularly reported by good operators. The increase in boiler-house efficiencies is necessarily small, because the law of heat transfer is fundamental. Progress has been in two directions: (*a*) Learning how to burn all the fuel at the best condition; and (*b*) adding heat traps to catch all heat not absorbed by the boiler proper.

---

[8] *Mechanical Engineering*, September, 1936, p. 539.

Prior to 1900, the heat engine was the steam engine of Watt and his successors. Unwin's figure of 12 lb of coal per ihp per hr (1880) had been reduced in the following 20 yr to less than 1 lb by increase of pressures and compounding, by going back to condensing practice, and by better workmanship. A compound engine with 1 : 7 ratio cutting off at 14% stroke in the high-pressure cylinder would give about 50 expansions, and water rates varying from 11 to 9 lb per ihp-hr were being guaranteed by many builders. Poppet-valves were used if superheated steam was furnished, but the ordinary Corliss valves could take care of 30° to 50° F of superheat. The main difficulty was the demand for large units; low-pressure cylinders as large as 110 in. were made. Sometimes, two low-pressure cylinders of 96 in. each were used, as in the engines of the Interborough Rapid Transit Company, at the 59th Street Power Station, New York, N. Y., where 8 000-kw units were installed. Rolling-mill engines with two 110-in. low-pressure cylinders developed as high as 25 000 hp. All these units were of comparatively low speed, to ensure continuity of operation and low upkeep.

Following 1900, came the steam turbine—in small units at first, but rapidly increasing in size to meet the growing demand for large blocks of power. The maximum size of individual units increased from 5 000 kw in 1903 to 20 000 kw in 1912; 60 000 kw in 1925; 110 000 kw in 1928; and 165 000 kw in 1929. A three-shaft unit of 208 000 kw was installed in the same year. It is now possible to build a larger single generator unit than 165 000 kw, but the demand has not yet developed. The early turbines did not have as good a water rate as the better engines, because high vacuums were not used; the 26 in. used by engines was thought good enough. The adoption of a 28-in. vacuum raised the number of expansions to 100, and the later increase to 29 in. doubled this figure, greatly increasing the efficiency and the unit capacity. To-day, designers strive for an absolute pressure of $\frac{1}{2}$ in. to $\frac{5}{8}$ in. of mercury, and water rates of approximately 9 lb per kw-hr, or 6.75 lb per hp-hr are common, even at ordinary pressures and with temperatures below 750° F.

Meanwhile, the Power Industry has learned the value of high pressure and high superheat. Pressure has been increased to 600 lb per sq in., then to from 1 200 to 1 400 lb, then to 1 800 lb, and, in Europe, installations using steam at the critical pressure (3 200 lb) are in operation. In temperature, 825° F is now standard, 932° F (500° C) is contemplated, and at least one unit has been in operation for some time at 1 000° F. Potter lists 16 stations carrying pressures between 710 and 1 840 lb; 25 stations between 500 and 700 lb; and 174 stations between 300 and 500 lb.

Table 1 shows the increase in thermal efficiency since Watt's time (1770). The first four entries are from a paper on "The Commercial Economy of High Pressure and High Superheat."[9] In this paper and the discussion that followed, the regenerative cycle, old in engine practice, was stressed, and since that time bleeding has become general practice. The predicted economies have been obtained. As many as six stages of feed-water heating have been used, and the feed-water is now heated nearly to the saturation temperature. Steaming economizers have been used, but the practice does not seem to be increasing. The most modern plants still fall short of introducing all the heat to the medium at the maximum temperature, although in the mercury vapor installations a larger proportion of the heat is introduced at approximately that point.

---

TABLE 1.—INCREASE IN THERMAL EFFICIENCY SINCE 1770

Year	Prime mover	Pressure, absolute	Temperature, in degrees Fahrenheit	Carnot cycle, actual percentage	British thermal units per kilowatt-hour	Thermal efficiency, percentage
1770	Newcomen engine	15	212	2.7	416 000	0.82
1810	Watt engine	30	300	9.17	61 000	5.60
1900	Nordberg engine	215	400	20.8	19 200	17.75
1922	Turbine	265	650	35.0	18 000	19.0
1935	Turbine*	1 245	825	58.0	11 166	30.6
1935	Turbine†	1 245	825	58.0	10 850	31.5
1935	Mercury vapor turbine	140	950	61.0	10 500	32.5
	Proposed mercury vapor turbine	240	1 025	63.5	9 500	36.0

* Port Washington, Wis., 8-month record, *Mechanical Engineering*, November, 1936, p. 697.

† Port Washington, Wis., record for single month, *Mechanical Engineering*, November, 1936, p. 697.

The cost of central stations has varied but little since Mr. Edison built the Pearl Street Station, in New York City. The writer's records, in more or less detail, cover more than 150 plants built between 1882 and 1936. The costs include land, buildings, foundations, water tunnels, coal and ash handling, boiler and turbine-room machinery and auxiliaries, the switching arrangements, and outgoing feeders to the building line. The average cost of these plants is substantially $100 per kw of capacity. Potter quotes figures collected by the Federal Power Commission, for 80 plants built since 1920, which average $108 per kw of capacity, while L. L. W. Morrow[10] lists 16 plants built since 1927 at an average cost of $114 per kw installed.

The average cost for the 250 plants in these three lists (with possibly some duplicates) is about $103 per kw of installed capacity. The installations are of many types—large and small, high- and low-pressure, light, power, and railway plants, with a small proportion of industrial plants. The lowest cost is about $60 per kw, and the highest, approximately $225 per kw. Potter lists 5 plants that cost more than $150 and 4 less than $70. Morrow's variation is from $82.50 to $145.00 per kw.

As a general rule, large plants cost a little less per kilowatt than small plants. High pressure plays little part; of the 1 400-lb plants reported by Morrow some were in the lower range of prices and some in the higher range. In favored locations, high-pressure stations have been built for as little as $82.50 per kw, and it is probable that this figure might be considerably smaller with later designs.

In the earlier years building costs were low, while machinery costs were high. Switchboards were simple and cheap. In later years, the electric costs have risen from 5% to as much as 25% of the total cost. (It should be noted that the cost of switchboard safety devices and other electrical equipment mounts rapidly with the size of the connected system.) Building costs, including cost of foundations, have increased from 10% to 40% of the total. Land has varied from 0.5% to 2.5 per cent. On the other hand, costs of machinery—boilers, turbines, piping, and auxiliaries—have decreased from 80% to 35% of the total.[11]

---

[10] *Electrical World*, November 23, 1935.

There is much diversity of opinion as to the cost as well as the desirability of "out-door" stations, and this is likely to continue until more actual experience has been obtained with the design, construction, and operation of this type of plant. Meanwhile, the convenience of operation and maintenance of the enclosed plant under severe weather conditions is likely to prevent much experimentation with the new design.

Central stations using steam as the heat medium are now in operation giving yearly economies, coal burned to kilowatt-hours sent out, of as low as 11 000 Btu per kw-hr—a thermal efficiency of 31 per cent. By taking full advantage of high pressure and temperature, carrying regeneration to the limit, and using at least one reheating stage, the thermal efficiency might be raised to about 37%, or the economy to about 9 200 Btu per kw-hr. With the mercury-vapor cycle, about the same economy might be obtained ultimately. Plants with such high efficiencies would be complicated in design and difficult of operation, as well as costly. They would require much better materials than are now obtainable, and are not even contemplated at present.

A steam plant running at 10 000 Btu per kw-hr, however, may be anticipated in the near future. The new heat-resistant materials, increased knowledge of the more common metals and alloys, the recent developments in boiler and turbine design, and the demand for more efficient plant, will bring it about.

The same economy is also in sight with the mercury vapor plants. A single month's record of 10 400 Btu per kw-hr was reported from the mercury plant, at Hartford, Conn., in 1936, and designs have already been made for plants with economies even lower than 10 000 Btu per kw-hr.

But are these very efficient plants justified? What is the relation between thermal efficiency and commercial efficiency? Thermal efficiency is easily measured. Fuel bills are plain, and present-day sampling and calorimetry are trustworthy. Station watt-meters are standard instruments and quite accurate. The two ratios, coal per kilowatt-hour and British thermal units per kilowatt-hour, are well known by all operators.

Commercial efficiency is a different story, for it involves many factors subject to conflicting interpretations. The cost of the installation may be book cost, replacement cost, or depreciated cost, or even cost minus some part charged off to steam heating, general offices, or rentable property. When this cost has been delimited, the percentage of fixed charges must be determined. This usually includes interest, reserve for renewals, taxes, and insurance, lumped together as 12.5% to 15% of the prime cost; and, then, enters the use factor of the installation. The average cost of stations is, say, $100 per kw. Fixed charges at 12.5% are then $12.50 per annum per kilowatt installed. If the use of the installation is 3 000 hr per annum, the fixed charges are 0.417 cts per kw-hr; if the use is 8 000 hr, the fixed charge is 0.156 cts.

---

[11] "Rôle of the Civil Engineer in Power Development," by the late Ira W. McConnell, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., January, 1928, p. 155; and the discussions by Messrs. P. Junkersfeld, Geo. A. Orrok, Joel D. Justin, and F. W. Scheidenhelm, published in *Proceedings*, Am. Soc. C. E., March, 1928, p. 923; J. A. Sargent, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., August, 1928, p. 1917; and the closing discussion in *Proceedings*, Am. Soc. C. E., for April, 1929, p. 977.

Operating charges also vary with the use factor, but not nearly to the same extent as fixed charges. With coal at the prices which ordinarily maintain on the Eastern seaboard, operating charges per kilowatt-hour may be expected to be less than fixed charges for uses of 4 000 hr, or less, per yr. Under conditions like those in the vicinity of Pittsburgh, Pa., the point of intersection may be as high as 7 000 hr. The total cost of power at the station wall is, of course, the sum of the fixed and operating charges. Hence, its magnitude always depends on the hours of use. In this connection see Table 2. It will be noticed that even with coal at $5 per ton, the fixed charges run from 36% of the total cost at 8 760 hr of use to 73% at 1 750 hr. Commercial efficiency increases with the use factor, and each plant presents a unique problem in which the prime cost of installation must be balanced against hours of use and fuel cost to secure the most favorable combination.

TABLE 2.—COST OF STEAM POWER*

Use factor, percentage	100	80	60	40	30	20	10
Hours of use	8 760	7 008	5 256	3 504	2 628	1 752	876
Fuel per kilowatt-hour, in pounds	0.773	0.777	0.786	0.804	0.821	0.857	0.964
Charges, in Cents per Kilowatt-Hour:							
Fixed	0.143	0.178	0.238	0.357	0.475	0.714	1.429
Other, except fuel	0.08	0.08	0.08	0.08	0.08	0.08	0.08
Total, all charges except fuel	0.223	0.258	0.318	0.437	0.555	0.794	1.509
Cost of coal, in cents per kilowatt-hour:							
Coal at $1.00 per long ton	0.345	0.0347	0.035	0.0358	0.0366	0.0382	0.043
Coal at $3.00 per long ton	0.1035	0.1041	0.105	0.1074	0.1098	0.1146	0.129
Coal at $5.00 per long ton	0.1725	0.1735	0.175	0.1790	0.1830	0.1910	0.215
Total cost, in cents per kilowatt-hour:							
Coal at $1.00 per long ton	0.2575	0.2927	0.353	0.4728	0.5916	0.8322	1.552
Coal at $3.00 per long ton	0.3265	0.3621	0.423	0.5444	0.6648	0.9086	1.638
Coal at $5.00 per long ton	0.3955	0.4315	0.493	0.616	0.738	0.985	1.724

* Conditions assumed: Cost per kilowatt of installation, complete, $100; no reserve capacity; fixed charges, 12.5%; plant economy, in British thermal units per kilowatt-hour, $10\,500 + \frac{30\,000}{\text{Use factor in percentage}}$; and heat value of coal, 14 000 Btu per lb.

The Power Industry has long known that the road to commercial economy lies in the extension of the hours of use of a given installation. Edison, Crompton, Wordingham, and other early authorities have made this fact plain to every maker of power. Balanced loads, steady running, and diversified services are sought by all, for power cannot be stored except at great expense. Unfortunately, however, the tastes and habits of users of power lead to a wide variation of load in industries and power supplies. In spite of this, however, load factors have grown. Edison, at Pearl Street, was well pleased with a 12% load factor. To-day, system load factors may go as high as 40%, while certain industries maintain a load factor of 70% or more; and the trend is toward a still larger use. With better load factors, the use of higher pressures and temperatures will increase, bringing higher efficiencies and a more general distribution of the benefits attained.

Improvement in the design and efficiency of the internal combustion engine has been steady and continuous, but because of the nature of the problem the advance has not been nearly so spectacular. Ever since gasoline has been available, Otto-cycle engines have been able to develop a brake-horse-power-hour on 0.6 lb of fuel; high-speed, high-compression aviation engines now give a brake-horse-power-hour on 0.4 lb of fuel.

The best Diesel engines of the World War years used 0.36 lb of oil per bhp per hr. Two-cycle Diesel engines did not do quite so well, and 0.4 lb of fuel was a good record for them in those days. Solid-injection engines of modern design do a little better than the earlier air-injection engines. The best record that has come to the writer's attention is 0.326 lb, attained by a two-cycle solid-injection Diesel. None of these figures includes the oil used for lubrication, a portion of which is burned in the cylinder and adds to the developed heat.

Solid-injection two-cycle engines are now the standard for all sizes, although four-cycle engines are still used in sizes up to about 2 000 hp, and air-injection designs are used where low-quality fuel is to be burned. The range between 0.32 lb and 0.4 lb of fuel is small, and the heat use ranges between 6 300 and 8 000 Btu per bhp per hr, or, putting the conversion factor at 700 watts to allow for generator efficiency, 9 000 to 11 400 Btu per kw-hr for the prime mover alone. Of the 60% of the heat lost in the exhaust and jacket, about three-fourths may be recovered; the main difficulty in the way of doing so is the cost and complexity of the apparatus required.

The range of thermal economies for the oil-engine plants is much the same as that for steam plants, but the lower limit is easier of attainment. At best, the internal combustion engine would appear to have an advantage of about 10% in thermal economy. On the other hand, the installation cost is usually much higher than for steam, the average cost per kilowatt being more than one-half again as large. No very large oil-engine stations have been built, the one at Vernon, Calif. (35 000 bhp, in five units) being the largest as of 1936. About 2 000 hp has been developed in the double-acting cylinder, and twelve cylinders on one shaft have been proposed. The large peak-load engines (Copenhagen), run at high piston speeds (more than 1 200 ft per min, so high that a long life is problematical). The best figures on internal combustion engine costs and operation are to be found in the reports[12] of the Oil Engine Power Cost Committee of the American Society of Mechanical Engineers.

The steam engine, as developed by Watt, his competitors and successors, made the Nineteenth Century the century of steam. Parsons, Delaval, Rateau, and Curtiss, and their successors, in the Twentieth Century have carried on their work. Otto, Clerk, and Diesel, following other lines, have brought about a tremendous development in transportation. Meanwhile, the binary-vapor proposals of the last hundred years have been put into material form by Emmet in the mercury-vapor turbine, which has already equalled the economy of the Diesel engine. All these developments lead one to speculate on what other forms of prime movers may be developed in the near future.

[12] *Transactions*, A. S. M. E., Vol. 57, p. 69.

On the basis of Milliken's electron theory and Rutherford's smashing of the atom a number of modern scientists and engineers have predicted that the next step will be atomic power—although Milliken's final summary on this question[13] is that power from atomic degradation can never be generated in commercial amounts.

In at least two locations (Llarderello, Italy, and Sonoma County, California), steam power is now generated by the heat of volcanic rocks, and Charles A. Parsons has proposed a well 12 miles deep to utilize the internal heat of the earth for the same purpose. The engineering difficulties of the latter proposal would be enormous, as the deepest wells to-day are less than 2 miles in depth.

In 1936 Dr. Abbott, of the Smithsonian Institute, at Washington, D. C., exhibited his solar engine, which utilizes Ericson's mirror system and is three to four times as efficient as former engines of this type. However, his apparatus is not comparable in size to Shuman's plants at Tacony, Pa.,[14] and Cairo, Egypt. The Tacony Plant, under test, developed 32 hp when the sun shone.

None of these proposals meets the criterion of a commercial power plant which must generate power when wanted, as wanted, and at a cost a little less than that at which it can be produced to-day. Engineers, scientists, and inventors are looking for a new source of power, convenient, plentiful, and cheap; but until that source appears it is certain that a major part of the world's power will be generated in heat engines using steam as the heat medium.

HYDRO-GENERATION OF ENERGY

BY FRANK H. ROGERS,[15] ESQ.

SYNOPSIS

The installed capacity of hydro-electric plants has been increasing almost continuously since 1900. Concurrently, the maximum size and horse-power of individual units have grown by leaps and bounds. The limit in efficiency was closely approached by 1920, and the most important event in the history of turbine design since that time is the development of the propeller-type turbine.

This paper reviews briefly the important design features of modern high-head, medium-head, and low-head turbines; discusses the importance of laboratory testing (with special reference to low-head installations); points to six important mechanical improvements in turbine design made since about 1925; and concludes with an examination of possible future developments, such as the pumped-storage plant and the use of the propeller-type turbine for higher heads.

Various aspects of the progress in the hydro-generation of energy in the United States since the beginning of the century are indicated in Fig. 1.

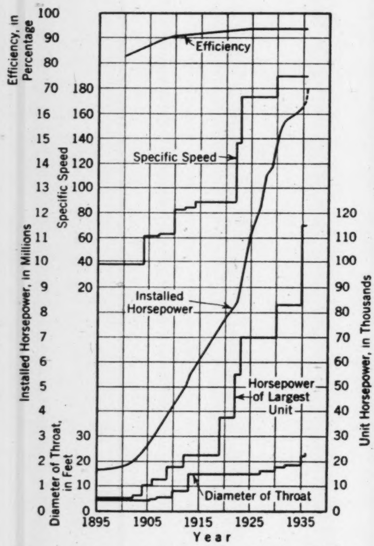

FIG. 1.—PROGRESS CHART OF THE HYDRAULIC TURBINE IN THE UNITED STATES, 1895–1936

As for installed capacity, it will be noted that from 1900, when the first developments at Niagara Falls were undertaken, there was a rapid increase until 1922, at the rate of about 300 000 hp per yr. Then the slope of the curve rose to a still higher rate of about 800 000 hp per yr from 1922 to 1931. In the next four years the increase in installed capacity fell off considerably, during 1935 amounting to about 100 000 hp. In 1936, however, a great increase occurred, about 1 500 000 hp capacity being installed, of which probably 800 000 hp actually went into operation before the close of the year.

The demand for larger units has been met by the use of better materials and new construction methods. The highest point on the unit horse-power curve indicates the 115 000-hp Boulder

---

[15] Chf. Engr., I. P. Morris Div., Baldwin-Southwark Corp., Philadelphia, Pa.

Dam turbines the most powerful units in the world. As for physical size (diameter of throat), the largest units yet constructed are those for the Bonneville Power Plant, in Oregon.

Since about 1910 a large majority of the turbines installed have been of the vertical-shaft type. This design has permitted the building of much larger units than would have been feasible with a horizontal setting. The development of the Kingsbury thrust-bearing about that time was the most important contribution to the success of the vertical unit.

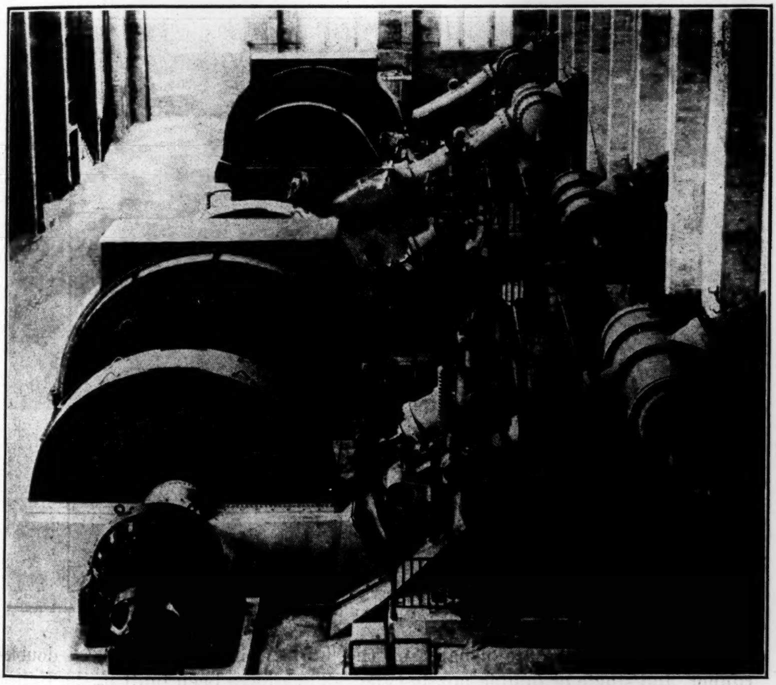

FIG. 2.—BIG CREEK NO. 2-A DEVELOPMENT, SOUTHERN CALIFORNIA EDISON COMPANY, WITH TWO 70 000-HP IMPULSE WHEELS

Little increase in efficiency has been secured since 1920, as the possible limit was closely approached at that time.

The increase in specific speed in 1922 is, however, noteworthy. In that year the large-sized propeller-type turbine, which permitted the economical development of large low-head plants, was introduced in the United States. This development is the most important in the recent history of turbine design, and this paper will devote considerable space to the problems involved in the design of this type of unit.

First, however, the progress made in the design of high and medium-head turbines will be reviewed briefly.

High-Head Turbines

The classification, "high-head turbines" is arbitrarily taken to include all units designed for heads greater than 300 ft. It comprises both turbines of the Francis type, and impulse wheels. For heads of 1 000 ft and higher the latter are used almost exclusively in spite of their lower efficiency and lower specific speed as in that head range cavitation limitations become critical, and the stresses involved in the casing and head cover would be excessive if the Francis type unit were used.

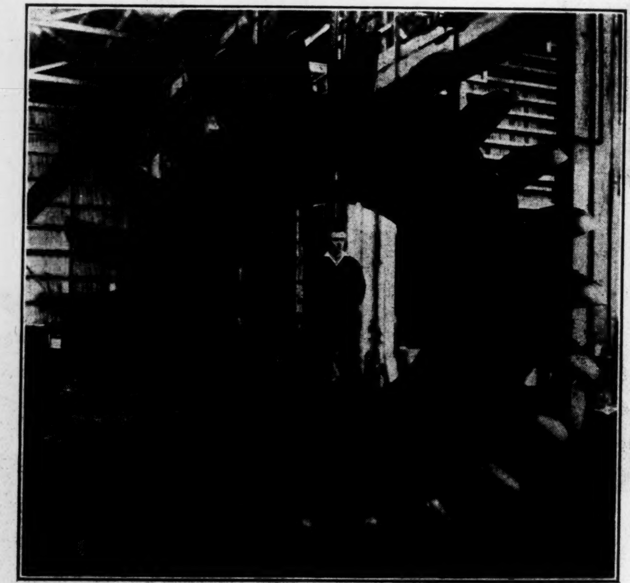

Fig. 3.—Runner, 162-Inch, for One of Big Creek No. 2-A Wheels

Impulse turbines are usually of the horizontal-shaft, single or double-runner, and single or double-nozzle type. They have been built in the United States in units as large as 70 000 hp, and for heads up to about 3 000 ft. Fig. 2 shows the two 70 000-hp impulse wheels of the Big Creek No. 2-A Development of the Southern California Edison Company. These units are of the two-runner, single-nozzle type, and operate under a head of 2 200 ft, at a speed of 250 rpm. One wheel of one of these units, with the buckets assembled, is shown in Fig. 3. The pitch diameter of the runner is 162 in. This unit is not only the largest in physical dimensions, but also the most powerful unit yet constructed for installation in this country.

Since about 1925 impulse-wheel efficiencies have been considerably improved by research in bucket and nozzle design. As an example, in Fig. 4 are shown one of the older elbow-type nozzles with relief nozzles below, and a straight-flow nozzle of improved design first developed in 1926. The water passageway in the latter, being perfectly straight, produces a jet with a minimum of turbulence and, consequently, of higher efficiency, and permits somewhat higher approach velocities to be used.

FIG. 4.—IMPULSE WHEEL NOZZLES; LEFT: ELBOW TYPE; RIGHT: IMPROVED STRAIGHT-FLOW TYPE

Reaction or Francis-type turbines have been used for heads up to about 850 ft. As examples of high-head Francis units the following may be mentioned:

30 000-hp turbine for the Big Creek Plant No. 8 of the Southern California Edison Company; head, 680 ft.

33 000-hp turbines for the Santeetlah Plant, of the Tallassee Power Company (now the Carolina Aluminum Company); head, 660 ft.

35 000-hp turbine for the Oak Grove Plant, of the Portland Electric Power Company; head, 850 ft.

49 000-hp turbine for the Waterville Development, of the Carolina Power and Light Company; head, 755 ft.

115 000-hp turbines for the Boulder Dam Plant, of the United States Bureau of Reclamation; maximum head, 590 ft.

The Boulder Dam units will operate under a wide range of head (420 to 590 ft), the average net head being 530 ft. At 420 ft each unit is guaranteed to deliver 90 000 hp, and at 480 ft and higher, 115 000 hp. Fig. 5 shows two of these turbines completely assembled in the shop. The casing has a 10-ft intake diameter, and was shop-tested to a pressure of 500 lb per sq in. One of the cast-steel runners, with an intake diameter of 14 ft 3 in., is shown in Fig. 6.

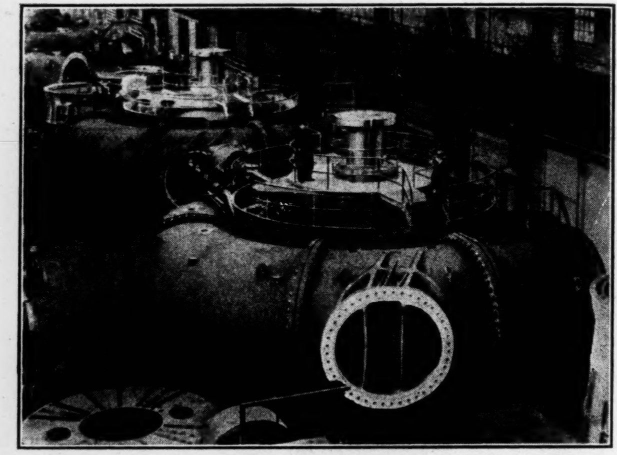

FIG. 5.—SHOP ASSEMBLY OF TWO 115 000-HP TURBINES FOR BOULDER DAM PLANT, OF THE UNITED STATES BUREAU OF RECLAMATION

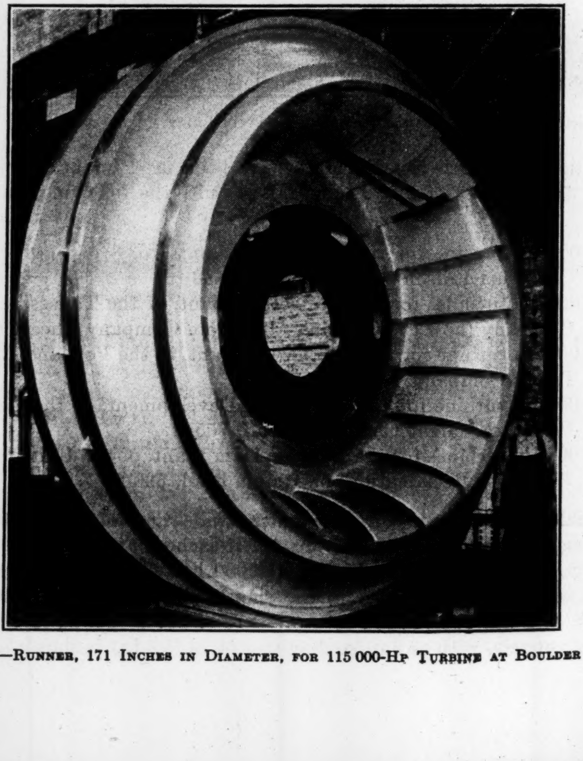

FIG. 6.—RUNNER, 171 INCHES IN DIAMETER, FOR 115 000-HP TURBINE AT BOULDER DAM

In high-head units especially, it is important to hold the leakage at the runner seals to a minimum. Any increase of the seal clearance due to wear materially affects the efficiency of the unit. A very close clearance can be used without danger of seizing due to contact, by adopting for the stationary seal an insert of soft metal such as Parson's white brass. Such a design (Fig. 7) is used in connection with two of the units of the Boulder Plant.

FIG. 7.—SEAL RING DESIGN FOR TWO OF THE BOULDER DAM UNITS

MEDIUM-HEAD TURBINES

For heads ranging from about 100 ft to 300 ft Francis turbines of the vertical-shaft, single-runner type are used. For the lower heads within this range the casings are of plate steel, and for the higher heads they are of cast steel. Noteworthy installations of this type include:

Seven 54 000-hp turbines—head, 89 ft—installed in the Conowingo Development of the Susquehanna Power Company, on the Susquehanna River, Maryland.
Two 66 000-hp turbines—head, 165 ft—installed in the Norris Dam Plant, of the Tennessee Valley Authority, on the Clinch River, Tennessee.
Three 70 000-hp turbines—head, 213 ft—installed in Station No. 3, of the Niagara Falls Power Company, on the American side of the Falls.
Two 83 000-hp turbines—head, 310 ft—installed in the Diablo Plant, of the City of Seattle, on the Skagit River, Washington.

Fig. 8 is a sectional elevation of one of the Conowingo units, with its butterfly valve. The runner has a throat diameter of 16 ft 2 in., and is made in four sections secured together by a crown plate and band. The casing, of steel plate, has an intake diameter of 27 ft. The butterfly valve is probably the largest ever constructed. During periods of low flow, this installation is a peak-load plant and the units are shut down for a considerable part of the time. For this reason, leakage past the butterfly valves is an important item, and in order to reduce it to a minimum these valves are provided with a special rubber tube sealing device. When the valve is closed, water under pressure is admitted to the tube, expanding it through a slot in the valve housing so that the rubber is in contact with the outside periphery of the valve disk.

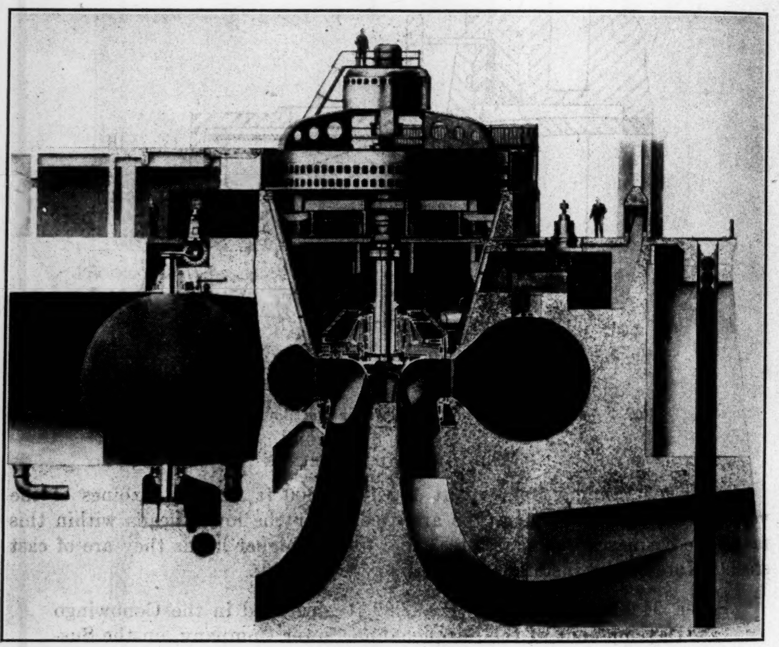

FIG. 8.—SECTIONAL ELEVATION OF 54 000-HP TURBINE, CONOWINGO DEVELOPMENT, SUSQUEHANNA POWER COMPANY

Fig. 9 shows the shop assembly of the plate-steel casing and cast-steel stay-ring of the Norris Dam turbines. The intake diameter of the casing is 17 ft 8 in. Fig. 10 is an interior view of the stay-ring, casing, and penstock of the installed unit, and clearly indicates the field riveting at the casing joints and the connection to the stay-ring.

The two-bearing unit with umbrella-type generator is an excellent design adopted in a number of installations. Fig. 11 shows one of the two 31 000-hp units of this type in the Morony Development, of the Montana Power Company, at Great Falls, Mont. Particular attention is called to the excellent design of the water passages. The penstock is straight from the intake gates to the casing, thus reducing to a minimum the losses at the intake and through

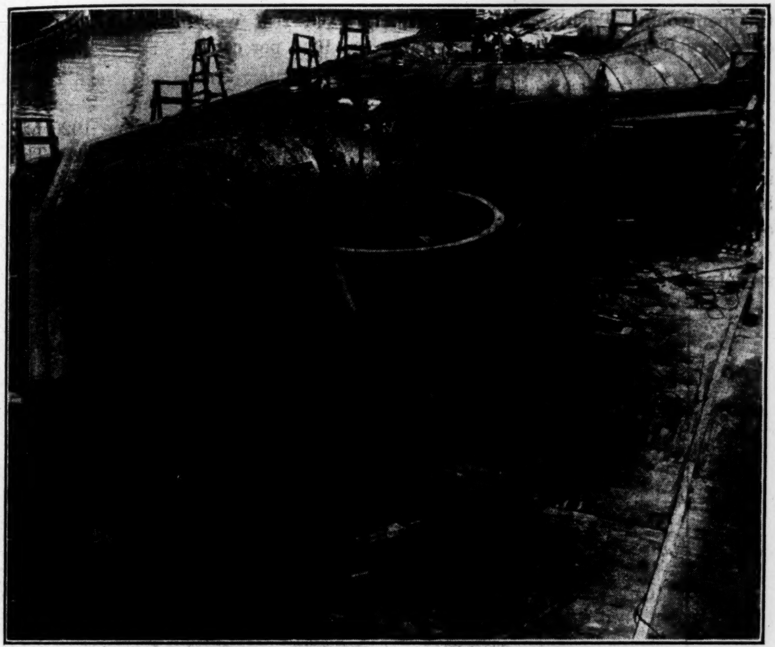

Fig. 9.—Shop Assembly of Spiral Casings and Stay-Rings of 60 000-Hp Turbines for Norris Dam Plant, Tennessee Valley Authority

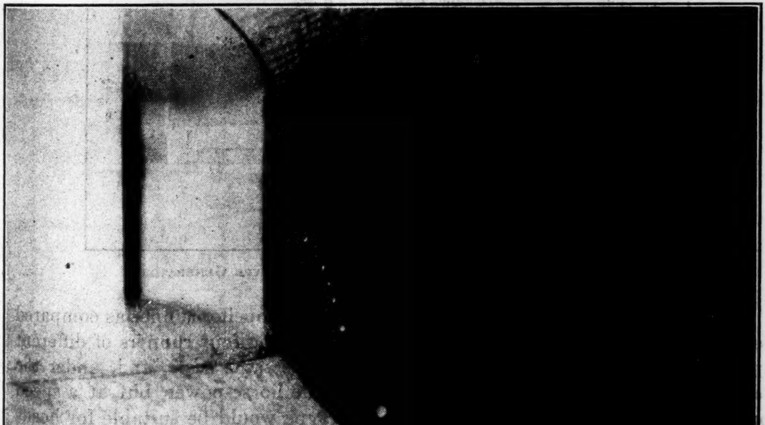

Fig. 10.—Interior View of Stay-Ring, Casing, and Penstock, Norris Dam Plant

the penstock. Turbine efficiency in the field test was 93%, and over-all efficiency from head-water to tail-water was 92.6 per cent.

LOW-HEAD TURBINES

The greatest advancement in hydro-generation of energy since 1920 has been due to the development of the high-speed propeller-type turbine. The increase in specific speed from about 90 for the Francis-type runner to 150 and higher for the propeller type has made possible the economical development of the large low-head installation, primarily by permitting the use of the lower-cost, higher-speed generator and reducing the cost of the power-house superstructure.

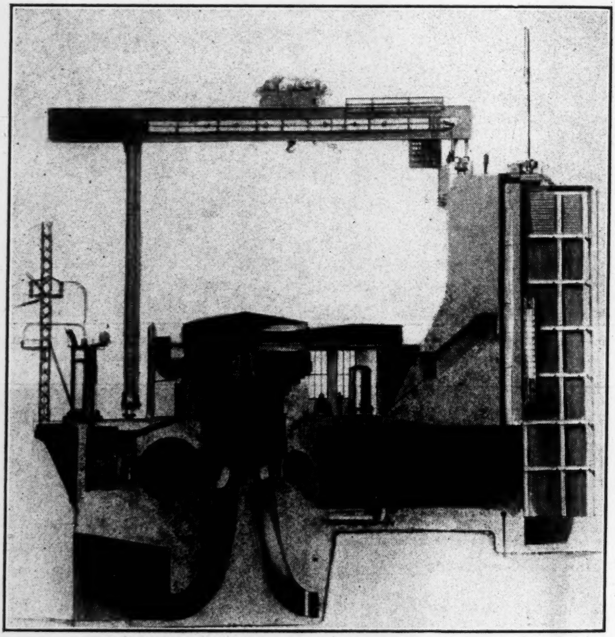

FIG. 11.—TWO-BEARING UNIT, WITH UMBRELLA-TYPE GENERATOR

The radical difference in size and shape of the propeller runner as compared to the Francis runner is shown in Fig. 12, illustrating four runners of different specific speeds. These runners are drawn to the same scale, and, under the same head, each runner would develop the same horse-power, but at a speed proportional to its specific speed. The first type would be suitable for heads up to 300 ft; the second, for heads up to 100 ft; and the last two, for heads up to 60 ft. It may be asked why the high-speed runner shown at the bottom cannot be used under the higher heads and thus obtain higher speeds for the generators. If this were attempted the velocity through the runner would be very high, and the absolute pressure would fall so low that vapor-filled cavities would form, the water would separate from the blades, and the resulting cavitation would not only reduce the power and efficiency, but cause pitting of the runner.

It is a general characteristic of turbine-runner design that, as the specific speed of the runner increases, the horse-power efficiency curve becomes steeper and the part-load efficiencies decrease. This characteristic is shown for the four runners of Fig. 12 in Fig. 13. It will be noted that for high-head installations where low specific speed runners are chosen, flat horse-power efficiency curves are obtained, whereas for low-head plants, where high specific speed runners are used, steep horse-power efficiency curves result. If it is necessary to operate the fixed-blade high-speed runner at part loads, a rapid falling off in efficiency will occur.

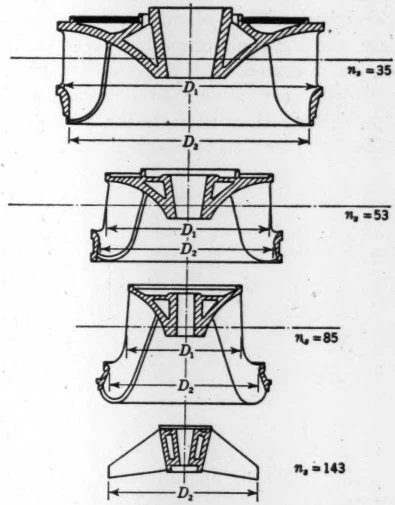

FIG. 12.—COMPARISON OF RUNNERS OF EQUAL POWER, BUT OF DIFFERENT SPECIFIC SPEEDS

This inherent weakness in the characteristics of the fixed-blade propeller turbine was overcome by the development of the adjustable-blade runner known as the Kaplan type (after Victor Kaplan, of Austria, who first suggested it). In this type of unit the runner blades and guide-vanes are automatically and simultaneously adjusted in accordance with the load demand to provide

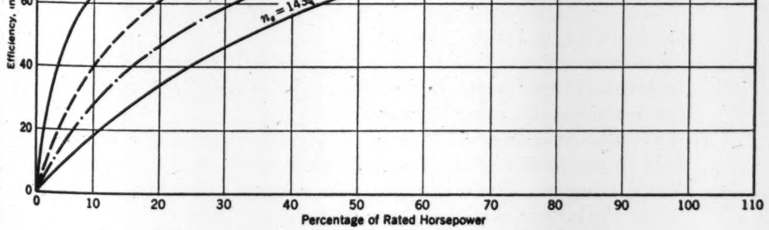

FIG. 13.—PERFORMANCE CURVES FOR RUNNERS OF FIG. 12

the best possible hydraulic relation between guide-vane opening and runner-blade position.

Fig. 14 shows a typical horse-power efficiency curve for the Kaplan-type turbine. Each of the dotted curves shows the performance of the unit if operated as a fixed-blade runner at the blade angle indicated. By automatically moving the runner blades at the same time as the guide-vanes the unit can be operated at the peak of each separate efficiency curve, so that the envelope curve (shown solid) becomes the real operating curve. The Kaplan-type turbine thus permits the adoption of high speed, yet maintains a high efficiency over a wide range in load.

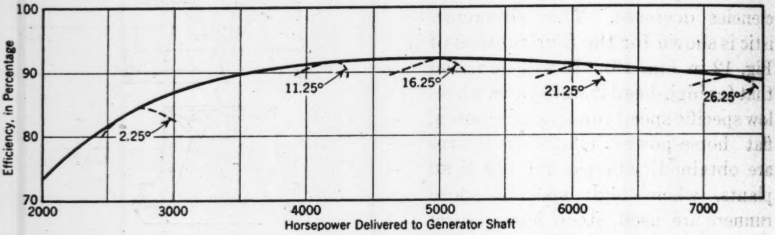

Fig. 14.—Typical Performance of Kaplan-Type Turbine

The following installations will illustrate the fixed-blade, propeller-type turbine:

Four 13 500-hp turbines—37-ft head—installed in the Louisville (Ky.) Plant of the Louisville Hydro-Electric Company.

Four 21 000-hp turbines—32-ft head—installed in the Rock Island Plant, of the Puget Sound Power and Light Company, Columbia River, Washington.

Two 45 000-hp turbines—48-ft head—installed in the Wheeler Dam Plant of the Tennessee Valley Authority, on the Tennessee River, Alabama.

Among the Kaplan-type installations may be mentioned:

Two 7 250-hp turbines—23-ft head—installed in the London and Marmet Stations of the Kanawha Valley Power Company, on the Kanawha River, in West Virginia.

Six 42 000-hp turbines—55-ft head—installed in the Safe Harbor Plant of the Safe Harbor Water Power Corporation, on the Susquehanna River, in Pennsylvania.

Two 48 000-hp turbines—43-ft to 56-ft head—being installed in the Pickwick Development of the Tennessee Valley Authority, on the Tennessee River, in Tennessee.

Two 66 000-hp turbines—69-ft head—being installed in the Bonneville Development of the Federal Government on the Columbia River, Oregon. These turbines, with a runner diameter of 23.3 ft, are the largest as well as the most powerful units of the Kaplan type as yet constructed in the United States.

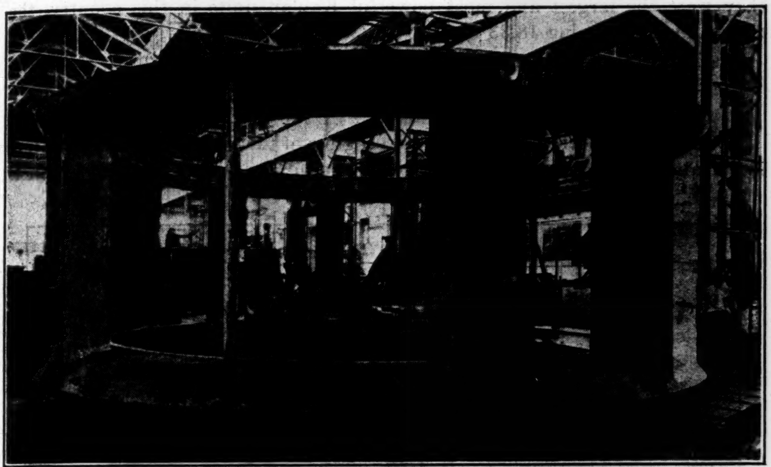

FIG. 15.—STAY-RING FOR 45 000-HP PROPELLER-TYPE TURBINE FOR WHEELER DAM PLANT, TENNESSEE VALLEY AUTHORITY

Fig. 15 shows the assembled stay-ring for one of the 45 000-hp Wheeler Dam units, and Fig. 16, the assembled runner for the same turbine.

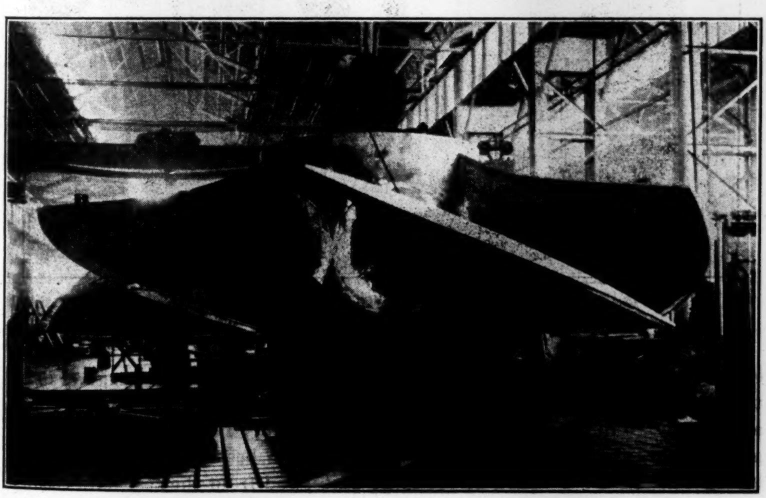

FIG. 16.—SHOP ASSEMBLY OF 22-FOOT FIXED-BLADE PROPELLER RUNNER FOR 45 000-HP, WHEELER DAM TURBINE

Fig. 17 is a sectional elevation of one of the 42 000-hp Kaplan-type turbines in the Safe Harbor Plant. At the time the first four units were installed (1931) they were the largest and most powerful Kaplan units in this country, the runner diameter being 18.33 ft.

LABORATORY TESTING

One of the important factors in the progress of turbine design and operation is the laboratory research carried on by all the turbine manufacturers. Models exactly homologous to the large units, including the intake, casing, and draft-tube, are tested over a wide range in power and speed. The model runners are usually 16 in. in diameter. Changes can readily be made in the runners, guide-vanes, casing, and draft-tube to obtain the best possible combination, before starting construction of the large units; and from the test data secured in the laboratory the performance of the large unit in the field can be accurately predicted. For the large low-head installations the intake, casing, and draft-tube are usually built by the power company in the concrete substructure, and the most efficient and economical design for the particular conditions at each

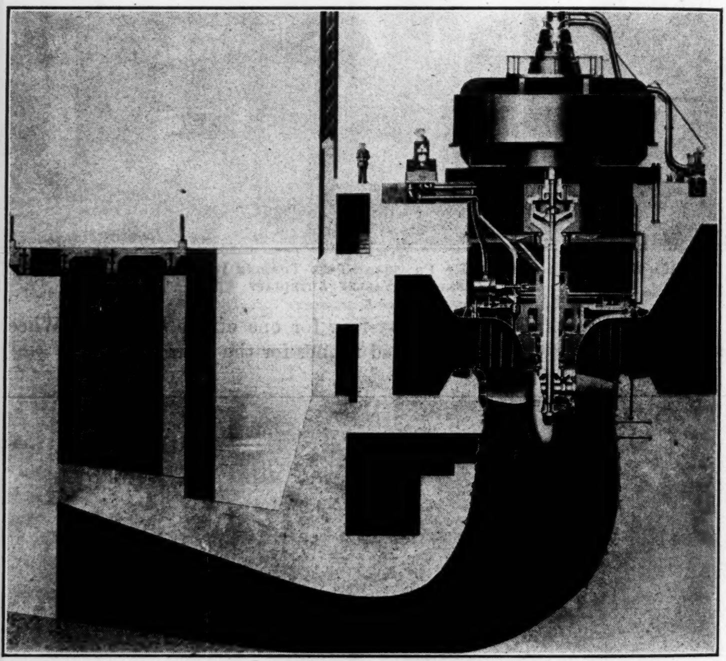

FIG. 17.—SECTIONAL ELEVATION OF 42 000-HP TURBINE, SAFE HARBOR PLANT, SAFE HARBOR WATER POWER CORPORATION

site can be determined from the laboratory test made in advance. Fig. 18 shows a model unit of the Boulder Dam turbines, and Fig. 19 shows the results of the laboratory tests made on it.

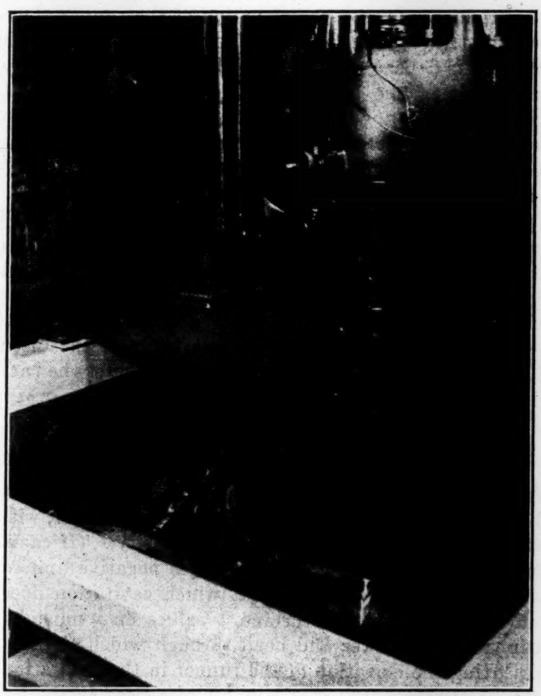

FIG. 18.—MODEL OF BOULDER DAM TURBINE

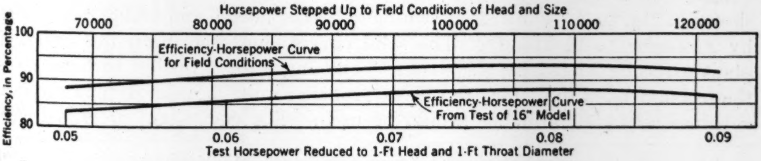

FIG. 19.—TEST RESULTS OF BOULDER DAM MODEL

Since the development of the high-speed runner the question of cavitation has assumed far greater importance than formerly, and much research has been devoted to it. Cavitation may be defined as the formation of vapor-filled cavities at points on the runner blade, or at any point within the water stream which disturbs the continuity of flow and causes the water to leave the blade surface. Cavitation reduces turbine efficiency; and due to the collapse or "implosion" of the cavities where the flow reaches points of higher pressure, causes pitting of the runner or adjacent parts.

At a given elevation above sea level and a given temperature, the absolute pressure available is the water barometric pressure. At the runner discharge this pressure is reduced: (1) By the elevation of the runner above tail-water; (2) by the velocity head; and (3), locally, by the curvature of the flow lines. This third element is dependent on the runner design, particularly on the proportional magnitude of the blade area and blade spacing, and may differ materially on two runners of the same specific speed. Hence, for any given runner, it is necessary to determine the correct elevation with respect to tail-water, so as to assure sufficient absolute pressure at the discharge of the runner blades under the required head in order to avoid cavitation.

For this purpose special cavitation laboratories have been built by several of the turbine manufacturers, and by the Pennsylvania Water and Power Company, at Holtwood, Pa., and the Shawinigan Water and Power Company, at Shawinigan Falls, Ont., Canada. In these laboratories the elevation of the tail-water can be varied while the total head on the model turbine is maintained constant. As the tail-water is lowered, observations are made of the discharge, power output, and efficiency; the break in these curves indicates the cavitation limit.

The cavitation coefficient, σ, is defined by:

$$\sigma = \frac{H_b - H_s}{H} \quad \text{.........................} \quad (1)$$

in which H_b = height of barometric water column; H_s = greatest elevation of runner above tail-water at which cavitation does not occur, with the turbine operating at a given percentage of its rated capacity. (If cavitation begins while the runner is still below tail-water, H_s is negative and represents the least depth of runner below tail-water at which cavitation does not occur.) H = total effective head on the turbine. Values of σ must be determined over the entire range of power and head through which the turbine is to be operated. In fixing the elevation of the runner in the field a factor of safety should always be allowed; that is, the value of σ used in the field should be well above the actual value determined in the laboratory.

Studies have been made of the behavior of various installations in operation, with particular reference to the avoidance of pitting, and several investigators have prepared curves to serve as a general guide to the selection of plant σ values. Such curves, for both the Francis and propeller-type turbines, are shown in Fig. 20.[16] The data shown have been collected and brought up to date by Professor L. F. Moody. The solid curves show the minimum values of plant σ recommended by the writer. The curve for propeller turbines gives the recommended limit for fixed-blade propeller units, but for Kaplan turbines σ values about 10% higher should be used. The curves are presented only as an approximate method of determining the elevation of the runner for a proposed installation; the final elevation should be fixed from the results of the cavitation tests made on a model of the runner to be used, or from field experience in homologous installations.

[16] In Fig. 20, "Rogers and Moody, 1925," refers to paper entitled "Inter-Relation of Operation and Design of Hydraulic Turbines," by F. H. Rogers and L. F. Moody, *Engineers and Engineering*, Engrs. Club of Philadelphia, 1925; "Rogers and Sharp, 1935," refers to paper entitled "45 000 HP. Propeller Turbine for Wheeler Dam," by F. H. Rogers and R. E. B. Sharp, *Mechanical Engineering*, August, 1935; "Scoville, 1936," refers to discussion by J. D. Scoville of paper entitled "Cavitation Testing of Model Hydraulic Turbines and Its Bearing on Design and Operation," by L. M. Davis, *Transactions*, A. S. M. E., May, 1936, p. 323; and "Scoville Discussion, Cavitation Tests," refers to test points derived from preceding reference.

MECHANICAL IMPROVEMENTS

Since about 1925 there have been many mechanical improvements in turbine design. Among them at least six are deserving of special mention:

(1) The use of stainless steel for those parts subject to mechanical wear and erosive action of the water is increasing. For example, stainless steel castings or forgings are used for the shaft sleeves of water-lubricated bearings and for the stuffing-boxes. Plates of stainless steel are used in some units to protect the top and bottom surfaces of the guide-vanes, for distributor plates, and on the periphery of propeller-type runner blades. Those parts of the runner-blade surfaces and throat rings most subject to pitting are in some cases protected by pre-welding with stainless steel.

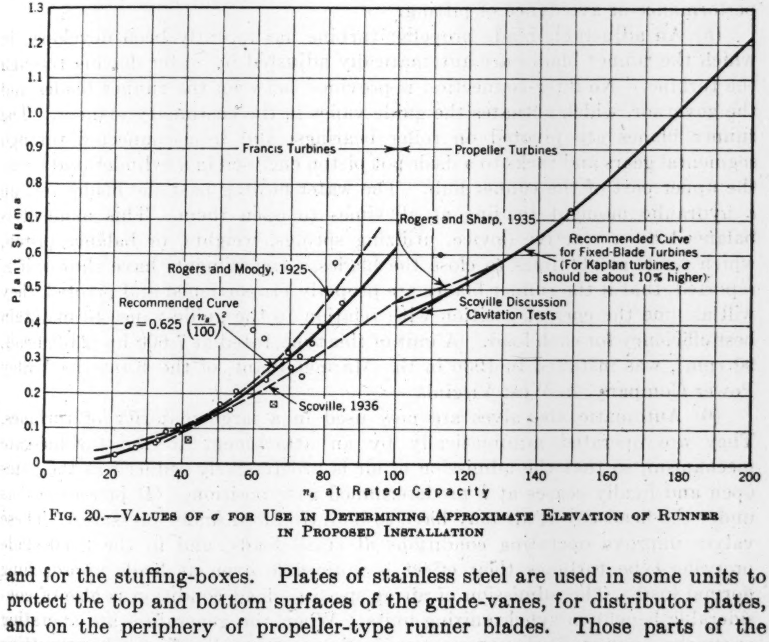

FIG. 20.—VALUES OF σ FOR USE IN DETERMINING APPROXIMATE ELEVATION OF RUNNER IN PROPOSED INSTALLATION

(2) Welded-steel construction has been used in some installations, for the guide-vanes, head covers, and stay-rings, in order to assure a more homogeneous metal than is obtainable with steel castings.

(3) Water-lubricated rubber-lined bearings have been used successfully in a large number of noteworthy low-head installations. This type of bearing was first used in one of the exciter units at the Holtwood Station of the Pennsylvania Water and Power Company, in 1924, and by 1936 about sixty of them were in use or under construction. They have proved superior to the usual

lignum-vitæ type in wearing qualities, particularly where abrasive matter is present in the lubricating water. Compared to the oil-lubricated, babbitted bearing, the rubber type is superior as regards operation, accessibility, and simplicity. It eliminates the inaccessible stuffing-box below the bearing, permitting the runner to be placed close to the bearing. The small lubricating pumps and water-drainage pumps required for the oil bearing are also unnecessary.

(4) The machining of blade surfaces of a propeller-type turbine (one of the units of the Safe Harbor Plant) has recently been tried. By this means it is possible to reproduce more accurately the curve and shape of blade desired than by the usual chipping and grinding to templates. It is not as yet possible to determine the actual benefit obtained by machining as regards either performance or avoidance of pitting.

(5) An adjustable-blade propeller turbine has recently been developed in which the runner blades are automatically adjusted by water flowing through the turbine. No inter-connection is provided between the runner blades and the governor, which actuates the guide-vanes in the customary manner. The runner blades are pivoted on roller bearings, and inter-connected through segmental gears and racks to a dash-pot piston enclosed in a cylinder that forms the upper part of the runner hub. The water flowing past the blades sets up a hydraulic moment tending at all times to open them. This moment is balanced by a reactive device, utilizing springs, weights, or balance piston, which tends at all times to close the blades. Experiments have shown, it is reported, that if the runner blades are properly proportioned and pivoted, they will assume the correct position with relation to the guide-vanes to maintain best efficiency for each load. A unit of this type, rated at 7 600 hp (23-ft head, 90 rpm), was installed in 1936 in the Marmet Plant, of the Kanawha Valley Power Company, in West Virginia.

(6) Automatic air-valves are now used in a large majority of turbines. They are operated automatically by an attachment to the turbine-gate mechanism, so that the admission of air is progressively reduced as the gates open and finally ceases at a predetermined gate position. (If pressure exists under the head cover, air may have to be introduced under pressure.) These valves improve operating conditions at small loads, and in the fixed-blade propeller-type turbines their effect is noticeable even at loads approaching normal load. The admission of air at speed-no-load condition is also of considerable benefit in synchronizing units. When the generators are operating as synchronous condensers, a great saving in power can be effected by admitting compressed air to depress the water until it clears the runner.

Possible Future Developments

At present, the Rocky River Development, in New England, is the only pumped-storage plant of any appreciable size on this Continent. However, the demand for reserve power and peak-power service, particularly near large load centers, has resulted in many studies of similar projects.

In the existing plant the motor-driven pump and the turbine-driven generator are separate units; but if and when any of the present proposals materialize, special turbine and pump equipment will be desirable to meet their requirements. Accordingly, at least one manufacturer has already designed and tested two model pump-turbine units which combine in one piece of apparatus the pumping and generating elements. This arrangement not only makes one machine do the work of two, but, in addition, does away with the elaborate hydraulic connections required when separate pumping and generating units are used. The adoption of such equipment will materially reduce the cost of pumped-storage plants.

The pump-turbine unit which has been developed is of the Francis type, with volute casing and movable guide-vanes surrounding the runner. The curves in Fig. 21 show the performance of the two model units as obtained by laboratory tests. (Both models had a diameter at the intake of about 18 in. and a throat diameter of about 12 in.) The high-head model has a specific speed, when generating, of about 26, and would be suitable for heads up to about 300 ft. The medium-head model has a specific speed of about 42, and would be suitable for heads of about 100 ft. It will be noted that when pumping, maximum efficiencies of about 85% and 87% were secured on the high-head and medium-head units, respectively; and that when generating, the maximum efficiencies were about 89% and 88%, respectively. In view of the dual performance required of the runner, these efficiencies are indeed excellent.

The two speeds required to give as nearly as possible the best efficiency for generating and pumping, respectively, are shown on the curves (Fig. 21).

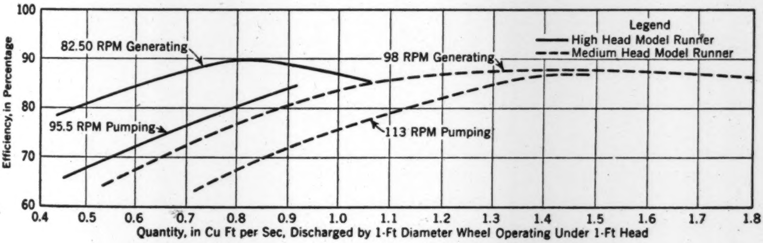

FIG. 21.—PERFORMANCE OF MODEL PUMP-TURBINE UNITS

This two-speed requirement may be met by the use of a two-speed type generator; one of the electrical manufacturers has carefully studied the requirements of such a machine and foresees no difficulty in building it. In some cases, however, it may be preferable to adopt a constant speed intermediate between the two values, and to sacrifice a small differential in efficiency.

Another promising field is the development of the propeller-type turbine for higher heads. The highest head to which this type has been applied in the United States is 69 ft (at the Bonneville Development, in Oregon). However, on the Shannon River, in Ireland, a Kaplan-type turbine has been installed to operate under a head of 106 ft. For these higher heads, runners with lower specific speed and large blade areas are required, in order to obtain low values of σ and thus avoid the necessity of locating the turbines at excessive depths below tail-water elevation. Undoubtedly, such runners will be developed to fill the gap in specific speed, between the present high limit of the Francis runner (85) and the low limit of the propeller-type runner (125). The economic advantage of higher speed as well as the better operating characteristics of the Kaplan turbine will certainly warrant the necessary research work along these lines.

With the inter-connection of large systems, automatic load control and frequency control have increased in importance. For any particular load on a station there is a most favorable division of power output between the separate units to secure minimum water demand or maximum over-all efficiency; and this optimum distribution between units can be maintained continuously and accurately only by automatic control. The same principle can be extended to load division between stations in a system. As to frequency, every station in a system must be controlled within very narrow limits. Further, if electric clocks are to operate satisfactorily, the cumulative errors caused by slight frequency changes must be compensated with a high degree of accuracy. Various devices have been developed to meet all these requirements, but further improvements and refinements in this type of equipment will undoubtedly be necessary to meet the severe demands of the large interconnected systems.

IMPROVEMENTS IN THE UTILIZATION OF ENERGY

BY JOEL D. JUSTIN,[17] M. AM. SOC. C. E.

SYNOPSIS

Recent development in the increased use and decreased cost of electrical energy is outlined herein. The paper traces the development of long-distance transmission, of regional power companies, of inter-connection between companies and of the co-ordination of steam and hydro-electric power development and shows the effect of these factors on the utilization of electrical energy.

Attention is directed to peak-load hydro-electric plants as a means of reducing the total cost of energy in a system, including both steam and hydro-electric plants.

Before the World War, power requirements of American communities were met, to a large extent, by local power companies. The major domestic use of electrical energy was for lighting. Its use in the home for refrigeration, washing machines, vacuum cleaners, etc., was relatively insignificant.

To-day, not only have all the old uses greatly increased, but additional uses for electricity in the home are constantly being found. The consumption per domestic customer has increased from an average of 268 kw-hr per yr in 1914 to 770 kw-hr for the year ending July 31, 1937.

CHANGES IN USE OF ELECTRICAL ENERGY

In 1914, manufacturing plants, to a considerable extent, owned and operated their own sources of power. American industry in that year purchased from central stations only 15% of its power requirements; and produced the remaining 85% in its own individually owned power plants. In 1936, by contrast, industry purchased about 53% of all the power it used and made in its own plants only 47 per cent.

Before the World War, a considerable percentage of all electrical energy produced was used in city and interurban electric traction; but now many of the interurban lines—and the trolley lines as well—are gone, and the electric traction load, except in the larger cities, is a relatively small percentage of the total load. There is, however, some indication that, in time, its place may be taken by the electrification of some of the steam railroads.

To-day more electrical power and less man power is being used by industry per unit of product. Electro-chemical industries, which are heavy users of energy, are being further developed. In the commercial field, there has been an increased use of electrical energy for better and more extensive lighting; and among the new uses of electricity, air-conditioning is rapidly assuming importance. A single large office building may require a motor installation of 3 000 or 4 000 hp for air-conditioning purposes alone. Stores and restaurants are finding it economically advisable to air-condition. If the present trend continues, within the next few years the office building or hotel that is not air-conditioned will be an obsolescent, low-rental structure. Air-conditioning of homes, although not yet an important factor in the increase of electrical load, will probably become so in time. The demand for it is beginning to appear.

---

[17] Cons. Engr., Philadelphia, Pa.

The increase in the variety of uses of electrical energy, the increase in the amount produced, and the decrease in the unit price, have been made possible by marked technical improvements in generation; and by a great advance in the adopted methods of utilization, whereby the maximum economic advantage of the generating facilities has been secured.

In Fig. 22 is shown the annual electrical energy output of privately owned public utilities for the period 1912 to 1936.

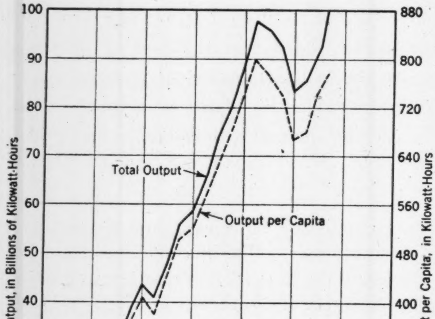

FIG. 22.—ELECTRICAL ENERGY OUTPUT OF CENTRAL STATIONS IN THE UNITED STATES, 1912-1936

DECREASE IN PRICE OF ELECTRICAL ENERGY

The increase in output of electrical energy has been paralleled by steady reductions in its price to the consumer. In 1914, the price of electrical energy for domestic use averaged 8.2 cts per kw-hr; in the year ending June 30, 1936, the average price was 4.51 cts per kw-hr, a decline of 45 per cent. By contrast, in 1935 the cost of living was approximately 40% higher than in 1914.

Only the privately owned public utility plants reporting to the Edison Electric Institute are included in the foregoing comparison. However, such plants account for from 94% to 95% of the total output of the United States.

CAUSE OF DECLINE IN PRICE OF ELECTRICAL ENERGY

Although Government regulation has been the cause of some individual rate reductions, the fundamental major cause of the decline in the price of electrical energy is economic.

Management, striving for greater total profits, worked for and obtained ever-increasing sales which, in turn, had a material effect in reducing costs. With the reduced costs, lower prices became possible. Lower prices stimulated greater use, and greater use permitted the introduction of more technical improvement. An endless chain whose links are technical improvement, decreased unit cost, decreased unit price, increased use, and increased total profits, was thus set in operation and has functioned successfully, with slight interruptions, to the present time. It will continue to operate to the advantage of all concerned (limited only by an apparently remote saturation point and the law of diminishing returns), unless one of the links in the chain is broken.

Community Power Companies

Prior to the World War there were relatively few regional power companies and their development was in its infancy. In general, each community or small group of communities was served by a local power company. Loads and plants were relatively small and transmission distances with a few exceptions were comparatively short. A 5 000-kw generator was considered a large unit in those days, and a 50 000-kw plant was a big one, such plants, for the most part, being confined to the larger centers of population. As there was not much inter-connection, the reserve requirements of individual systems were high, and it was not unusual for power companies to have installations equal to 150% or even 200% of their peak load for any given year.

Steam Companies and Hydro-Electric Companies

Before the World War power companies might have been divided into two classes: (1) Those utilizing steam as their main source of power, often referred to as steam companies; and (2) those utilizing water power as their main source of power, often referred to as hydro-electric companies. The useful hydro-electric installation plus the necessary machine reserve for any given water power company was limited to that for which there was always sufficient stream flow available to produce enough power to serve the peak load. Even so, the hydro-electric companies, at times, would have available energy which they could not use on their load curves. This surplus, which was produced at off-peak periods and during seasons of high stream flow, was sold to neighboring steam companies. This policy required the construction of inter-company transmission lines, and enabled the steam companies to shut down some of their steam generating units, at times, and thus save fuel.

Improvement in Long-Distance Transmission

The opportunity for utilizing low-cost surplus hydro-electric energy at important industrial centers, served largely by steam-generated electric power, put a premium on the development of the long-distance transmission of electrical energy. At the same time, it was found that some sources of hydro-electric power could be developed economically to serve primarily a distant load center, provided the cost of transmission was low enough.

These factors were largely responsible for the development of long-distance transmission. Voltages were stepped up from 66 000 to 110 000 and then to 220 000, and with the increases in capacity which these high-tension lines permitted, the cost of transformation, regulation, and control was decreased per unit of energy transmitted. Technical improvements in the generation of power by both steam plants and hydro-electric plants also led to material decreases in cost.

Regional Power Companies

A rapid growth in sales followed, and the "set-up" of the community power company proved to be an inefficient means of handling the increasing business with its extensive distribution over wide territories, and its need for rapidly increasing capital expenditures and for co-ordinated operation between the various units.

Consequently, regional power companies became more prevalent. Community power companies joined together or were absorbed to form integrated and co-ordinated systems, many of which served territories hundreds of square miles in area, with populations of several million people. The resulting economies, as indicated by the decreasing price of the product, have been very material. During the years of the great depression the tendency was retarded, but is again becoming evident with a return of more normal conditions.

Inter-Connection

Inter-connection developed coincident with the growth of regional power companies. By inter-connection, as herein used, is meant the tying together, by means of high-tension transmission lines, of two or more independently operated power systems. The economies of inter-connection ensue from savings in investment in additional generating facilities and from savings in operating expense. Against such savings must be set the increased fixed charges and operating expense for the additional transmission facilities.

Extensive economies have been attained through many of these inter-connections. On the other hand, there have been some in which the increased annual cost of the inter-connection has exceeded the annual savings so far attained thereby. Every proposed inter-connection should be carefully analyzed to determine its potential economies.

Between 1920 and 1930, there was a rapid growth in inter-connection. In some cases very large inter-connected systems (like that shown in Fig. 23[18]) were built up, and industrial centers with a combined load of 1 000 000 kw, or more, were tied together with high-tension transmission lines. Territories covered by such systems sometimes exceed 20 000 sq miles and include populations of several million people. The power companies forming such inter-connections or power pools have entered into agreements for the purpose of operating the combined system to secure maximum economy in capital expenditures and in annual operating costs. This inter-connection of independently operated properties made little progress during the depression and even in 1937 had not been greatly revived.

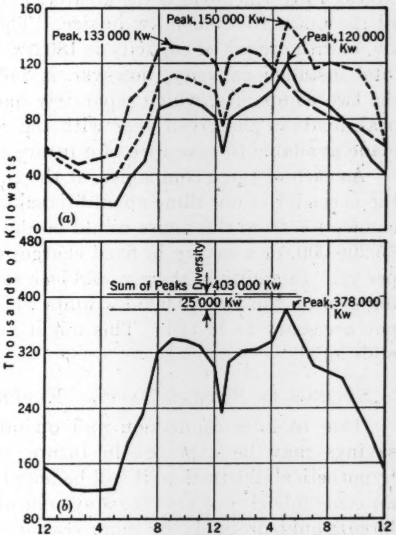

FIG. 24.—DIVERSITY OBTAINED BY INTER-CONNECTION: (*a*) PEAK DAY LOAD CURVES OF SEPARATE COMPANIES; (*b*) PEAK DAY LOAD CURVE AFTER INTER-CONNECTION

SAVINGS DUE TO LOAD DIVERSITY THROUGH INTER-CONNECTION

The load characteristics of various companies may differ materially. The load curve of a company serving a metropolitan district is very different from that of a company serving small centers and rural areas, and the load curve of a company serving an area in which heavy industries predominate will probably be very different from either of the first two. Thus, one company may have its seasonal peak in October, whereas another near-by company may have its annual peak in December. There may also be a material diversity in the daily load curves, one company having its daily peak load much earlier in the day than the other; and even where companies serve communities of a similar character, there is almost always some "incidental" load diversity—that is, a diversity for which there appears to be no special reason but which, nevertheless, occurs year after year.

If companies having load curves like those just discussed are inter-connected and operated as a single economic entity, either with or without identity of ownership, it is obvious that the combined system will not require as much installed capacity as would be the case without such inter-connection. Fig. 24 shows the load diversity obtained by a typical inter-connection of three companies.

---

[18] Adapted from an illustration in "Power Supply Economics," by Joel D. Justin and William G. Mervine, John Wiley & Sons, Inc., New York, N. Y., 1934.

Reserve Capacity Savings Due to Inter-Connection

Assume that two hypothetical power systems are considering inter-connection. Each has an annual peak load of 100 000 kw, and each is served by a steam plant having an installed capacity of 120 000 kw, consisting of six 20 000-kw units, one unit in each plant being in reserve. It will be assumed also that the total load diversity between the two companies is 20 000 kw. Then, if the two companies are inter-connected and operated as an economic entity, the combined load that must be served will be 100 000 + 100 000 − 20 000 = 180 000 kw. In this case, experience has determined that the required reserve must be equal to 10% of the peak load, or to the capacity of the largest unit, whichever is the greater. Of the peak load 10% is 18 000 kw, and all the units are 20 000 kw in size. Therefore, the required reserve is 20 000 kw, and the required capacity is 180 000 + 20 000 = 200 000 kw. The actual total installed capacity, however, is 240 000 kw. Thus, by inter-connecting the two companies, which separately had only enough capacity to serve their peak loads in the given year with the required reserve, a surplus capacity is made available to take care of a future growth of 40 000 kw in the demand.

As each of these companies, at the time of inter-connection, was faced with the necessity of installing an additional 20 000-kw unit, the saving due to inter-connection from this cause would be the capital sum of, say, 40 000 × $130 = $5 200 000, or a saving in fixed charges of, say, $5 200 000 × 0.14 = $728 000 per yr. In addition, there would be a saving of the fixed portion of the operating cost on the two 20 000-kw units which, because of inter-connection, it was not necessary to install. This might amount to as much as $100 000 per yr additional.

Savings in Future Capital Expenditures with Inter-Connection

Due to inter-connection and operation as an economic entity, material savings may be expected in future capital expenditures. Continuing the hypothetical illustration, it will be noted that, whereas 20 000 kw was probably an economic size of unit for a system with a 100 000-kw load, a unit twice as large would probably be more economical for a system with a peak load of 180 000 kw.

Therefore, when the growth in the load of the combined system requires additional capacity, the requirements may be met by installing units of 40 000-kw capacity each. The capital cost and operating cost of such units would be considerably less than those of the 20 000-kw units which the companies were in the habit of installing prior to inter-connection. The additional annual saving might be material.

Saving in Allocation of Plants to Load Through Inter-Connection

It will be assumed that the base load of the individual companies (that is, the load which is continuous throughout the 8 760 hr of the year) is 20% of the peak load. The base load of the combined system will thus be 40 000 kw. The several units of any system practically always vary materially in efficiency, largely because of the difference in their age. It will be assumed that one of the two companies has three units which are much more efficient than any of the other units in either system (all units having a capacity of 20 000 kw).

With the combined load due to inter-connection, these three units could operate on a much higher annual capacity factor—that is, they could operate more hours per year at full capacity. The less efficient units would operate correspondingly fewer hours per year. Such operation would reduce the average unit production cost of the combined system, producing an additional annual saving. Fig. 25 shows the allocation of units to the load demand for a typical day, before inter-connection, for the company possessing the three highly efficient units. It is evident that, after inter-connection, the base load would be twice as great as that indicated in Fig. 25 and the three efficient 20 000-kw units would then be able to operate at an annual capacity factor approaching 100 per cent.

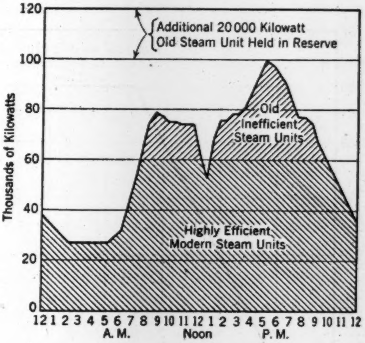

FIG. 25.—ALLOCATION OF PLANTS TO LOAD, BEFORE INTER-CONNECTION (FOR COMPANY WITH THREE HIGHLY EFFICIENT UNITS)

ANNUAL SAVINGS DUE TO BETTER USE OF HYDRO-POWER WITH INTER-CONNECTION

Many engineers think of steam and hydro-power as competitive sources of electrical energy. Occasionally, they are competitive, but over wide areas of the United States they are more usually complementary. It has been found that a system whose power supply is derived from both steam and hydro-power plants in proper proportion will have a lower over-all cost of power supply than a system otherwise identical but served solely by steam capacity.

Assume the same two hypothetical companies as before, but for one of the 20 000-kw steam units of one of the companies substitute a hydro-electric plant with an installed capacity of 30 000 kw. Further, assume that stream flow and pondage conditions are such that, at time of peak load, this plant can be relied on for a firm capacity of only 20 000 kw when operating on the load curve of the one company alone. (Firm hydro-electric capacity may be defined as that part of the total installed capacity of a hydro-power plant which, under existing conditions of load, stream flow, and pondage, is capable of performing the same function in serving the part of the load curve allocated to it, that an alternative steam plant could perform.)

As the magnitude of a load curve increases, there is a lesser amount of energy in the upper part of the load curve for any given number of kilowatts in the peak of the load. Consequently, when the two companies are inter-connected, it is found that all the installed hydro-electric capacity of 30 000 kw is firm capacity on the combined load curve.

Fig. 26 illustrates this growth of firm hydro-electric capacity. In order to plot such a diagram two preliminary steps are necessary: First, a "load-duration curve," with loads as ordinates and time as abscissas is plotted. Areas under the curve thus represent energy. By planimetering, or otherwise, energy for various numbers of kilowatts, measuring down from the peak, is determined. Second, a "peak percentage curve" is plotted using the information thus obtained. For this curve, the ordinates are the percentage of total load (measuring down from the peak) and the abscissas are the percentage of total energy for the period down to this given point. Using this curve and knowing the peak load for the given year, the energy required to serve any given part of the load may be obtained. After the peak percentage curve is plotted, the curve of Fig. 26 can be constructed readily. In some cases it may be necessary to investigate other periods than the peak-load week.

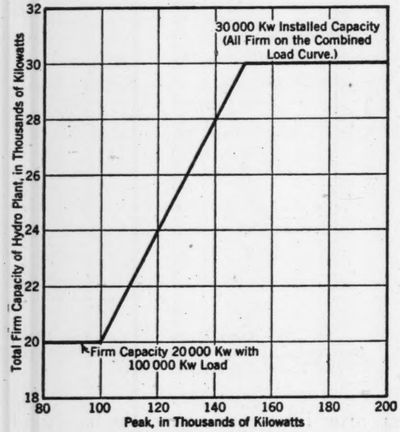

FIG. 26.—INCREASE IN FIRM CAPACITY OF 30 000-KW HYDRO-ELECTRIC PLANT WITH INCREASING SYSTEM LOAD

From the preceding discussion it is evident that by inter-connection the firm capacity of the hydro-electric plant has been increased by 10 000 kw, and that the effective capacity of the combined system has also been increased by 10 000 kw (in addition to the 40 000-kw increase previously mentioned). The corresponding capital saving of, say, $1 300 000, would accrue at such time as the companies would otherwise have had to install at least that much additional capacity.

The inter-connection of the two systems also gives an opportunity to utilize more nearly all the energy that the hydro-electric plant is capable of generating with the existing installation and the available stream flow. Without inter-connection, the base load on which the hydro-electric plant can operate continuously at periods of ample stream flow is only 20 000 kw, and, consequently, during a considerable part of the time, a large part of the available hydro-electric energy must be wasted. On the other hand, when the systems are inter-connected, the base load becomes 40 000 kw, and when ample stream flow is available the hydro-electric plant can operate continuously on the base without waste of energy.

The improvement in the utilization of available hydro-electric energy throughout the development period of the regional power companies has been very marked. Many individual power companies, with a high percentage of hydro-electric installation, had hydro-electric utilization factors of from 35 to 60 per cent. (The utilization factor is the ratio of the energy actually produced by a hydro-electric plant to the energy that could have been produced by the same plant during the same period, if there had been a market for it.) Now that these companies have been absorbed into large regional power systems, and the plants are inter-connected with load centers served largely by steam, the annual utilization factors of the same hydro-electric plants have risen in many cases to more than 90%, and, in a few cases, to practically 100 per cent.

Utilization of Peak-Load Plants

Supplying energy for the peak load of any power system is always very expensive as compared to the average cost of electrical energy. It is not unusual for the top 20% of the annual load curve to contain only from 0.5 of 1% to 1% of the total annual energy output of the system. Thus, a plant serving this part of such a load curve might have an annual capacity factor of from 1¼% to 2 per cent. As the average annual capacity factor of the system as a whole may be 35%, it is evident that the cost of providing the peak-load service may be a great many times the average total cost of energy.

In many systems, peak-load service is performed by the more antiquated steam plants in the system. Their high cost of energy production does not greatly matter because they produce very little energy. However, the maintenance and operating cost, which it is necessary to incur in order to have them ready to operate when required, and the cost of keeping them in "hot reserve" for a part of the time, are frequently high.

Peak-Load Hydro-Electric Plants

The possible improvement in the utilization of energy and the reduction in the total cost of power supply, through the use of peak-load hydro-electric plants in large regional power companies and in inter-connected systems, does not always receive the attention it deserves. The operating and maintenance cost of a hydro-electric plant is low as compared to that of a steam plant. Further, the hydro-electric plant can be put on the line at a moment's notice, thus making feasible a reduction in the amount of "hot" reserve that must be carried at the steam plants of the system.

Hydro-electric plants with ample pondage and a very high ratio of installation to available stream flow are particularly suitable for performing this peak-load service. For base load service the steam plant is generally a much cheaper source of energy. A high installation ratio usually means a low over-all cost per kilowatt of capacity, since the major part of the total investment is usually in the power plant itself ($50 to $70 per kw of installation) and the investment per kilowatt in dams and flowage is relatively small.

The economic advisability of using hydro-electric plants of the peak-load type for performing peak-load service is indicated in Fig. 27. For comparative purposes, the total unit cost of the energy output of a relatively modern steam plant, using cheap fuel, is shown by Curve *A*. Curve *C* gives the capital cost of an alternative hydro-electric plant for peak-load service, based on actual and fairly typical experience, and Curve *B* gives the total unit cost of its output. The principal assumptions are indicated in Fig. 27.

The decline in the capital cost of the hydro-electric plant per kilowatt of capacity with a decrease in the annual capacity factor actually reflects the fact that the average cost per kilowatt for a hydro-electric plant generally decreases rather rapidly with an increase in installed capacity. Although the incremental cost of steam-plant capacity is also frequently much less than the average, this holds only until the predetermined maximum capacity of the plant is reached; further, the tendency is not nearly so marked as in the case of hydro-electric installations.

It should be noted that for an annual capacity factor of 5% the total cost of energy from the hydro-electric plant would be 1.7 cts per kw-hr, while at the steam plant the total cost per kilowatt-hour would be 4.0 cts. For lower annual capacity factors the discrepancy is still greater. Although the comparison is quite typical it would vary materially for any individual case.

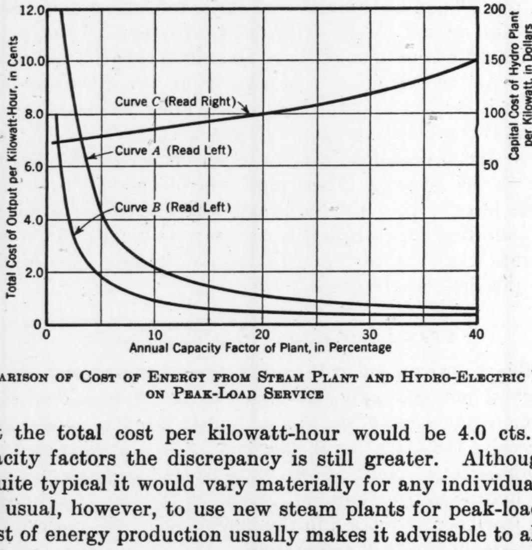

FIG. 27.—COMPARISON OF COST OF ENERGY FROM STEAM PLANT AND HYDRO-ELECTRIC PLANTS ON PEAK-LOAD SERVICE

It is not usual, however, to use new steam plants for peak-load service, as their low cost of energy production usually makes it advisable to allocate them to the base load or, at any rate, to some point lower down on the load curve. For old steam plants on peak-load service, interest charges on the investment in them should not be considered in comparisons such as the foregoing. In most cases, the fixed part of the annual operating cost for old steam plants is high enough to make up for the omission of interest charges, with the result that the comparison is frequently not any more favorable than that indicated in Fig. 27.

Run-of-river hydro-electric plants, when provided with ample pondage, are also used for peak-load purposes during periods when the stream flow is low; provided, of course, that the relation of low-water stream flow to load is such that they will be firm capacity on the load curve. It is believed that peak-load hydro-electric plants will find an increasing application, as there are many systems in which their more extensive use would prove economic. Their development, however, is limited by the availability of suitable sites near large load centers. The cost of a long transmission line, added to that of the plant itself, might more than offset the economies.

Pumped-Storage Hydro-Electric Plants

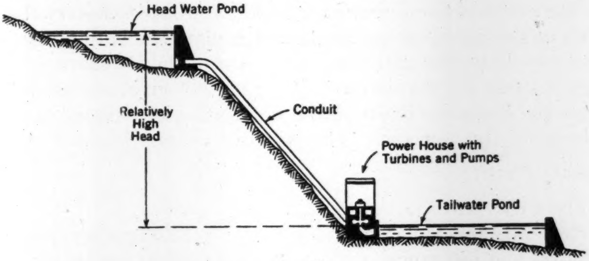

Fig. 28.—Typical Pumped-Storage Hydro-Electric Plant

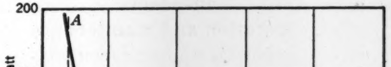

Fig. 29.—Economic Limitations of Pumped-Storage Plants to Replace Old Steam Plants with 15% Annual Capacity Factor

The pumped-storage hydro-electric plant is simply a special case of the peak-load hydro-electric plant, the main difference being that for the pumped-storage plant no source of water supply is required. In such installations the cost of spillway dams is minimized or eliminated. All that is required is a site for a pond or reservoir in the hills, another one at lower elevation, and a sharp drop between. In its simplest form (Fig. 28[18]) the pumped-storage plant consists of a head-water pond, penstocks, a power-house with turbines and pumps and a tail-water pond. "Make-up" water to take care of seepage and evaporation may be furnished by a brook or may be pumped from a distance. At peak-load periods, when the plant is in demand, water flows from the head-water pond through the turbines, generating power. During low-load periods, when the plant is not in demand, low-cost off-peak steam-generated energy or surplus hydro-electric energy flows to the plant and pumps the water back into the head-water pond, and the plant is then ready for another peak-load period. In Europe, there are thirty or forty such plants in successful operation, functioning as storage batteries for various power systems, but in

America there is only one—the Rocky River Development of the Connecticut Light and Power Company, near New Milford, Conn., with a capacity of 24 000 kw. In that plant, incidentally, the tail-water is a river instead of a pond.

Where suitable sites exist near large load centers, pumped-storage plants offer a means of reducing the cost of peak-load service and, hence, the total cost of power supply. In some such cases it will be found economical to use them to replace the antiquated steam plants already performing peak-load service. In order to make such a change economically desirable it is necessary that the total annual cost of the proposed pumped-storage plant, including interest on the investment, should be less than the annual cost of the old steam plant without considering interest on the investment. Fig. 29[18] gives curves indicating to some extent the economic limits in the application of pumped-storage hydro-electric plants for this purpose. The principal assumptions are:

Old Steam Plant:

Fixed charges	0
Renewals and replacement	$2.00 per kw per yr
Taxes and insurance	$2.50 per kw per yr
Incremental cost of energy	5 mills per kw-hr

Pumped-Storage Hydro-Electric Plant:

Fixed charges	(See Fig. 29)
Over-all efficiency	60%
Operation and maintenance	$1.00 per kw per yr
Renewals and replacements	1% on capital cost
Taxes and insurance	1% on capital cost
Off-peak energy for pumping	2.2 mills per kw-hr

In Fig. 29, the point where Line *AA* cuts each curve gives the maximum permissible cost for the pumped-storage hydro-electric plant, if the net return on the investment is to be 7 per cent.

As there are many situations where the fixed part of the operating cost of old steam plants is within the range indicated in Fig. 29, it is evident that there is room for a further application of pumped storage in the United States.

PENDING DEVELOPMENTS

In a rather general manner, this paper has discussed means of utilizing to the greatest economic advantage various technical developments in the electric-power field. With the resumption of industrial activity at an accelerated pace further technical advances may be expected.

One such advance that might produce radical improvements in the utilization of electrical energy, is long-distance direct-current transmission. A system of this type is already in experimental use between the Schaghticoke Hydro-Electric Plant of the Niagara-Hudson System and Schenectady, N. Y. Some electrical engineers are quite optimistic about its possibilities. They visualize the possibility of obtaining thereby the economic transmission of electric power to much greater distances and at considerably less cost than is possible with alternating-current transmission and transformation. The development of huge Government power plants remote from the load centers provides an additional inducement for such a development.

However, even without such startling developments as this, much will still be accomplished in the way of a better and more economical utilization of existing power-supply resources. In the existing inter-connections and power pools it has been found that, where there is an identity of ownership, the interconnected properties come much closer to taking advantage of all the economies that are theoretically possible. Hence, with the resumption of industrial activity there will doubtless be a resumption of further inter-connection and consolidation on a territorial basis to the advantage of consumers and power companies alike.

COST OF GENERATION OF ELECTRIC ENERGY

BY PHILIP SPORN,[19] M. AM. SOC. C. E.

SYNOPSIS

This paper is a general discussion of the subject of the cost of electric energy, with particular emphasis on the cost of generation and the related items of transmission and distribution. It covers the economics of steam power *versus* water power and shows that, in most cases, present-day steam power can be produced more cheaply than present-day water power. It shows that there is no economy in long-distance transmission of electric energy and that sound economics require the location of the generating plant near the load. The cost of distribution is presented briefly, emphasizing the point that this item is the major cost in expenditure for electric service.

The paper concludes that the trend in cost of producing, transmitting, and distributing electric energy is downward—although no sharp dip is to be expected—and that future power requirements will be met by steam plants located economically with reference to loads.

INTRODUCTION

The cost of generating electric energy is only a small part of the total cost of electric service, which must also include transmission and distribution. Current technical and political-economic discussion on the cost of electric service is largely out of focus because this fact is not fully realized. More particularly is it neglected in much of the discussion on the cost of the generation of hydro-electric power by governmental agencies. In many cases, it is assumed that the apparently lower cost of generation of hydro-electric power can and will result in a much lower cost of electric energy to the consumer.

This, of course, is not the case. Hydro-electric power is not necessarily cheap power, and, in most cases, is not competitive with steam power. Nevertheless, it cannot be denied that the cost of generation is an item, and sometimes an important item, in the total cost of power.

The writer, in this paper, will attempt to clarify various factors in the cost of generation by different types of prime mover. It must be borne in mind that the costs are presented from a general viewpoint. The problem, of necessity, is complicated, and, within the scope of this paper, only rough studies and outlines are possible. The main object, however, has been to determine the approximate boundaries and trends of generation cost.

PRESENT COSTS OF ELECTRICAL ENERGY

The sources of energy used commercially to-day are falling water—that is, hydro-electric power—and fuels, either in steam plants or in internal-combustion plants. Internal-combustion plants, however, have such limited application in so far as central stations are concerned that they will not be discussed herein.

---

[19] Vice-Pres. in Chg. of Eng., Am. Gas & Elec. Service Corporation, New York, N. Y.

Investment Cost of Hydro-Electric Power.—Hydro-electric power has received a great deal of attention since 1933, particularly because its development has been pushed vigorously in connection with various governmental projects; and the impression has spread that, as it involves only the harnessing of "natural" power, its cost cannot be equalled by any other method. That the actual facts seldom warrant any such assumption is known to a few, but certainly is not generally realized. Most of the favorable hydro-electric sites have already

* Power available 90% of the time.

† 10.75% of costs shown in Columns (8) and (9).

‡ Assuming that all the installed capacity is firm at 40% load factor. This assumption is necessary since Federal Power Commission data do not show actual annual kilowatt-hour output at all of these sites.

been developed, and any analysis of existing developments is likely to present a too optimistic picture of what is available at the remaining sites.

An analysis of fifteen hydro-electric plants is shown in Table 3. The data in Column (1) through Column (7) are taken from various Annual Reports of the Federal Power Commission, and are used to compute the entries in the remaining columns. The assumptions made are stated in the footnotes.

An examination of Table 3 discloses: First, the extremely high cost per kilowatt of primary capacity even among the lowest-cost projects of the fifteen analyzed; and, second, the wide variation between the highest and lowest costs. The unit costs on the basis of primary capacity are perhaps somewhat higher than they would have been if additional capacity beyond the primary had not been installed. However, the cost per kilowatt on an installed-capacity basis is still very high, running from $124 to $348. The fixed charges show variations from 0.342 ct per kw-hr to 4.56 cts per kw-hr on a 90% load-factor basis, and from 0.380 ct per kw-hr to 1.067 cts per kw-hr on a 40% load-factor basis.

All this definitely shows: (1) That hydro-electric energy, far from being "free," involves fixed charges that, in many cases, are well in excess of the fixed charges and operating costs of steam power; (2) that the costs are not predictable from general experience and knowledge of the art of generation, but depend on such factors as head, topography, stream flow, and location; and (3) that hydro-electric plants, in general, as a source of primary power, are out of the economic range. The true economic function of hydro-electric power is, without doubt, to supplement steam power. This point is covered in the paper by Mr. Justin.

Operating Cost of Hydro-Electric Plants.—The cost of operating hydro-electric plants represents only a small portion of the total cost, the preponderant portion being the fixed charges on investment, as previously discussed. Operating costs at a particular plant are more or less a fixed item and substantially independent of the kilowatt-hours produced. A recent study of operation costs of plants of various sizes is summarized in Table 4. It will be seen that the median value on the basis of the annual cost per kilowatt installed varies from $2.80 to $0.68, depending upon the size of the plant. The maximum and minimum values are $8.00 and $0.50 per kw per yr, respectively. Based upon an annual load factor of 40%, this represents a kilowatt-hour cost of from 0.8 mill to a low of 0.19 mill.

TABLE 4.—OPERATING COSTS OF HYDRO-ELECTRIC PLANTS

Installed capacity, in kilowatts	Operating Costs, in Dollars, per Kilowatt of Installed Capacity per Year			Median value of operating costs, in mills, per kilowatt-hour at 40% annual load factor
	High	Low	Median	
Up to 10 000..........	8.00	0.90	2.80	0.80
10 000 to 25 000.......	3.18	0.70	1.40	0.40
25 000 to 50 000.......	3.00	0.60	0.98	0.28

100 000 to 200 000.....	1.65	0.50	0.68	0.19

Steam Power Investment Costs.—The general range of costs of steam plants has been fairly well established. L. W. W. Morrow found[20] that in one group of sixteen plants built between 1924 and 1927, the range in cost, including step-up sub-station equipment, was from $101 to $180 per kw, the average being $139 per kw, and in another group of sixteen plants, built since 1927, the range was from $82.50 to $145 per kw, with an average cost of $114 per kw. From other data in possession of the writer on an even greater number of plants, the range of costs for steam plants built prior to 1932 was found to be from $85 to $140 per kw of installed capacity, with the greatest number of plants comprising the greatest amount of installed capacity falling within the range of from $100 to $110 per kw. There are some "sports" below and above the limits of $85 and $140. One plant is reported to have cost less than $70 per kw, but this was an unusual situation; in a power system supplied in the main by hydro-electric plants, economy in steam generation was properly sacrificed to some extent in order to obtain the maximum capacity at the minimum cost. Also, in this as in a number of other very low-cost installations, the so-called "framework" features that normally are associated with a steam-power development were omitted.

The wide variation in costs thus found makes it apparent that no rational deduction can be drawn as to the "average" cost per kilowatt of steam plants. Therefore, in preparing Fig. 30, the writer has used capital costs per kilowatt of $100, $115, and $130, as being representative of the costs of existing steam power plants. The annual fixed charges forming part of the total cost data in Fig. 30 were based on these capital costs. No separate investment values are plotted in Fig. 30, the two sets of data actually plotted being operating costs and total costs.

Steam Power Plant Operating Costs.—The operating costs of a steam electric power plant, unlike those of a hydro-electric power plant, form a large part of the total cost of generating. This is illustrated by Fig. 30. In this diagram the three upper curves, A_M, B_M, and C_M, show the total cost of generation at annual load factors from 10 to 90 per cent. These curves were obtained by adding the annual fixed charges per kilowatt-hour calculated at a rate of 12.75% to the annual operating costs per kilowatt-hour. An analysis of steam power plant operating costs—fuel, labor, and maintenance—discloses that for the same load factor the variations in cost per kilowatt-hour are just as wide as the investment cost.

The central station industry of the United States operates approximately 22 000 000 kw of steam generating capacity. Of this amount, more than 11 000 000 kw were installed in the years between 1923 and 1930. In that period great strides were made in the art of steam power generation, affecting the efficiency in the use of fuel and labor. This 11 000 000 kw of capacity, being the newest and presumably the most efficient, is undoubtedly generating the bulk of the power sold to-day. However, it would be just as fallacious to say that the cost in the latest plant is representative of operating costs as it would be to say that the costs in the earliest plant were representative. The answer lies somewhere in between. Curve *M* is an attempt to show the average operating cost and was derived after study of the costs of many representative plants.

---

[20] *Electrical World*, October 27, 1928, and November 23, 1935.

The curves in Fig. 30 show clearly the effect of load factor on costs. At low load factors, say 30%, operating costs constitute only a little more than 33% of the total cost (using $115 as the capital cost), while at 80% load factor, operating costs make up 50% of the total cost.

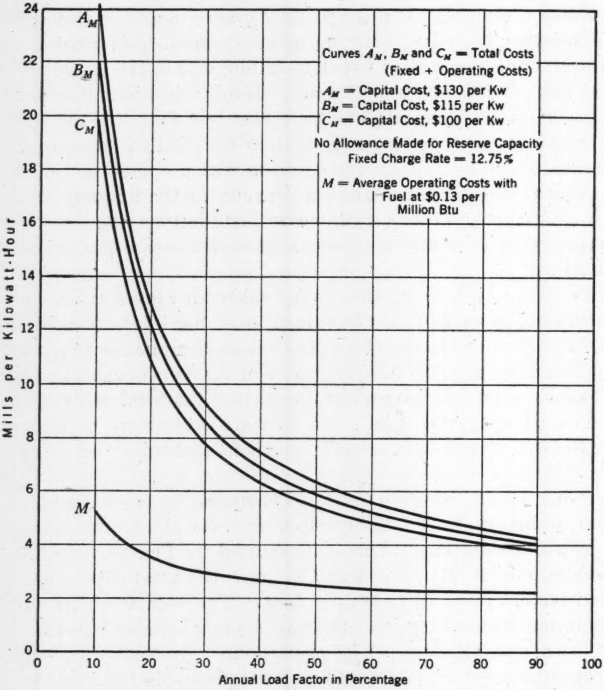

FIG. 30.—GENERATING COST OF STEAM-ELECTRIC STATIONS. THESE CURVES SHOW BASE-GENERATING COSTS AT GENERATING STATION

Cost of Transmission.—One of the most misunderstood factors in the cost of power is the cost of transmission. Those who have studied the problem closely and thoroughly understand the economics of power supply have been for the most part unable to find any sound economical basis for long-distance transmission of power. In general, power is most economical when generated nearest the load, and beyond a certain distance transmission definitely is not an economical proposition. Except in isolated cases, such as those where fuel is not easily available and sources of hydro-electric power are remote from the load, long-distance transmission of power is not practical. Hence, in economically developed supply systems transmission has been used largely as a means of integrating relatively small loads into reasonable blocks in order to take advantage of their diversity and to make possible economical generation within a limited load area.

Unfortunately, the collection of specific data on this subject is extremely difficult. An attempt is made herein, however, to present some definite data, even though they are approximate.

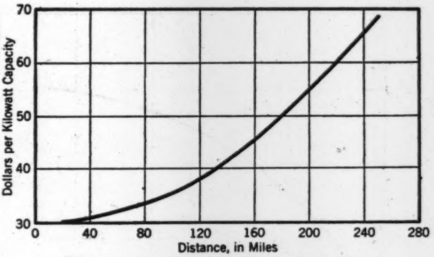

FIG. 31.—COST OF TRANSMISSION LINES

In Fig. 31 the cost of transmission lines, in dollars per kilowatt of capacity, is plotted against distance. Two points in connection with this curve are worthy of note: First, the tendency of the cost per kilowatt to flatten out as distance is materially decreased (this is due to the heavy cost of terminal equipment); and, second, the rapid climb of the curve, at distances of more than 200 miles, to costs approximating those of modern steam plants.

In Fig. 32 there is plotted a series of curves showing cost of transmission, in mills per kilowatt-hour, against transmission distance, in miles, for load factors of from 30 to 90 per cent. Fixed charges, taken at 12.25%, include 0.75% for operation and maintenance. The interesting point in connection with these curves is the rapid increase in the cost of transmission with increase in distance and, particularly, with decrease in load factor. Thus, at a load factor of 50% and a distance of 250 miles, the cost of transmission per kilowatt-hour is approximately that of the operating cost of generation alone in existing modern steam plant practice (see Fig. 30).

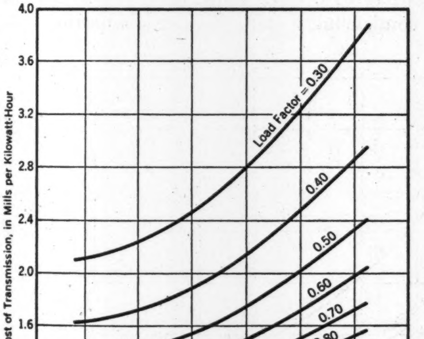

FIG. 32.—COST OF TRANSMITTING ELECTRICAL ENERGY, INCLUDING CHARGES ON TERMINAL EQUIPMENT

In Fig. 33 average freight rates per net ton of coal are plotted against airline distances. These rates are based on published freight tariffs as of October, 1936, for the shipment of coal from typical coal-producing areas to coal-consuming destinations. From these data, calculations have been made of the cost, in mills per kilowatt-hour, of transmitting energy, either as coal by freight or as electric energy. The assumption is made that coal costs $1.50 per ton and that 1 lb of this coal will produce 1 kw-hr, and that fixed charges on transmission facilities are 12.25 per cent. Losses of 10% for the transmission of electric energy have been included. The results are shown graphically in Fig. 34.

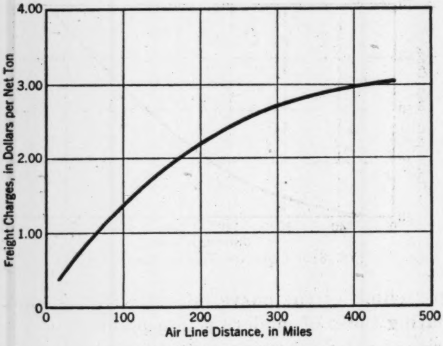

FIG. 33.—COAL FREIGHT RATES

It will be noticed that except for very high load factor operation at distances of 140 miles, or more, freight transmission is more economical than electrical transmission. At load factors of 50% and less, the economy of freight transmission is particularly great. As distances are shortened a point is reached where the choice between freight and electrical transmission cannot be made solely by comparing transmission costs, since the location of the steam station (with regard to condensing water, in particular) is a major consideration: but where choice is at all free, it is obvious that it should be in almost every case in favor of freight as against electrical transmission. The actual economic distance will vary, of course, somewhat with local conditions, particularly as regards the facilities for supplying condensing water. In this connection, it is

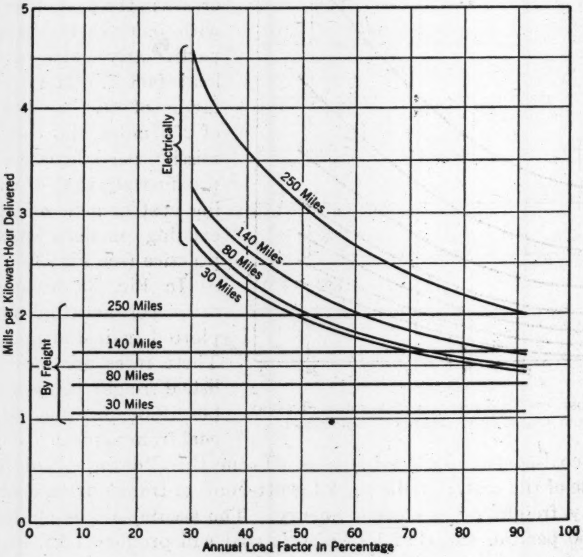

FIG. 34.—COMPARISON OF COST OF TRANSMISSION OF ENERGY BY FREIGHT (COAL) AND ELECTRICALLY

interesting to note that on the American Gas and Electric Company's interconnected system, extending over nine States and serving about 1 200 comparatively small communities, the actual mean weighted distance of transmission under normal conditions is less than 60 miles—notwithstanding that conditions over a large part of the area (Ohio and Indiana) are extremely unfavorable from the standpoint of availability of condensing water. This definitely illustrates the fact that although inter-connection may be economically sound, long-distance transmission has no such solid economic foundation.

Cost of Distribution.—A discussion of the cost of distribution is beyond the scope of this paper. However, the point needs to be definitely impressed that, at least for residential and general factory use, the cost of distribution is the major cost of energy, despite many recent improvements in distribution facilities. In Fig. 35[21] is shown a nest of curves giving the cost of distribution, in cents per kilowatt-hour (excluding the cost of energy), for different customer densities and for average customer use of from 200 to 2 000 kw-hr per yr. It will be seen that as customer use increases these costs come down to a fairly reasonable figure, running to a low at 2 000 kw-hr of from 1 ct to 2 cts, depending upon the customer density. However, as the customer use decreases, this cost may run to as high as 10 to 20 cts per kw-hr, at very low customer densities and customer use.

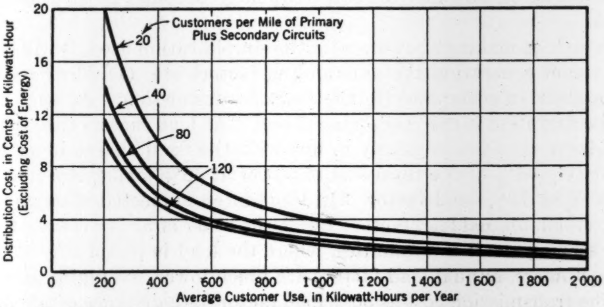

FIG. 35.—RELATIONSHIP BETWEEN CUSTOMER USE AND COST OF DISTRIBUTION FOR VARIOUS CUSTOMER DENSITIES

Total Cost of Generation.—By taking the total cost of generation as the cost of generation at the source, plus the cost of transmission to the load center, the present total cost of generation by steam plants can be obtained for any particular situation, from a combination of the data given in Figs. 30 and 32, within fairly definite limits. On the other hand, it must not be forgotten that in some respects these data have been obtained by simplifying the problem considerably beyond what is practical in an actual system.

For instance, if any electric power system is to furnish adequate and reliable service, it must provide reserve generating equipment. In Fig. 30, in developing the fixed charge item of cost, no allowance was made for reserve capacity.

---

[21] "Rational Distribution of Electric Energy and Gas," by Norman R. Gibson, M. Am. Soc. C. E., World Power Conference, Washington, D. C., 1936.

In actual practice on an isolated power system with only one plant, as much as 50% of the installed capacity (100% reserve) may be required to insure continuous service. This may even double the cost of the firm capacity in the plant, that is, the capacity available for sale. Even in an inter-connected system having many generating plants, some part of the installed capacity is needed for reserve. The actual amount may vary from 15% to 30%, depending on the size of the units, the magnitude of the load served, and a number of other factors. This reduction in reserve is obtained by building inter-connecting transmission lines, and their cost must also be considered in any discussion of generating costs.

Likewise, in an actual system, transmission and distribution are frequently so closely interwoven—both lines and equipment being commonly used to perform a dual function—that an exact allocation of equipment and costs between transmission and distribution frequently becomes most difficult, if not impossible.

Nevertheless, making allowance for the simplification used, it will be noticed that for steam generation the outstanding factors are: (1) The fixed charges; (2) the production costs; and (3) the cost of transmission. At very light load factors the first item is the predominant one. As load factors rise, the production cost item comes more nearly in line with the fixed charge item, becoming approximately 60% of the total cost of power at 50% load factor and approximately 50% at 70% load factor. In large inter-connected systems serving a diversified load, annual load factors are on the order of 55 per cent. In isolated systems, serving small communities, where the load is principally that of residential customers, annual load factors are much lower, averaging about 35 per cent. The transmission cost at 50% load factor for a distance of 200 miles may substantially equal the cost of production, and for greater distances may well exceed it.

It is extremely difficult and perhaps unfair to attempt a direct comparison of costs between a single hydro-electric development and a steam plant. On the other hand, this assertion itself discloses the weakness of the typical hydro-electric development, since as a general rule no hydro-electric plant is self-sufficient. This being the case it is impossible to determine its value without considering the position it takes on the load curve, and its effect on costs of other producing sources. In general, this is a point that must be thoroughly considered before a decision as to economic feasibility of a particular hydro-electric project can actually be made.

Another way of stating this is that the hydro-electric plant does not have as much flexibility as regards load factor as the steam plant. The latter can be designed for use at high load factor, and assigned, successively, to positions on the load curve of lesser and lesser use as more economical steam plants are developed. Such shifting is impossible in the case of a hydro-electric plant, which, in general, can be developed economically only for a certain position on the load curve. Its economics are adversely affected when it is used on any other basis. In this connection the data on transmission costs shown in Fig. 32 are pertinent. When proper evaluation of the cost of transmission is made, it is obvious that the economics of hydro-electric generation are bound to be less and less sound as fuel sources are made available within reach of main load centers and as the more economical hydro-electric sites are exhausted.

FUTURE COSTS OF GENERATION OF ELECTRICAL ENERGY

Trends in Steam Generation.—From the analysis of costs previously given, it appears that one of the most important factors in lowering steam plant generation costs is the reduction of investment costs. The trend in cost of generating equipment has been definitely downward, although admittedly the trend curve has not had a very steep slope. However, there is a definite promise in the direction of, first, higher steam temperatures; and second, the use of higher speeds (which will eventually mean more efficient use of materials).

Installation of larger steam generators, in particular, offers material opportunities for reducing costs in the future. The economics of these large units, however, is contingent upon increasing the availability factors of steam generating units. Recent installations have shown availabilities as great as 94.5%, but a definite step will be made when steam generating equipment can be consistently designed and operated at availability factors of 95 per cent.[23]

Another factor tending to reduce generation cost is superposition in existing steam plants. As a general rule, however, superposition has to be handled in fairly large blocks if it is to be economical. In other words, it is of value primarily where the base loads are heavy and the load factors high. Fortunately, increased co-ordination in the generation programs of inter-connected systems can bring about an economical application of super-position in many cases where an independent program may not prove entirely feasible.

Trends in Hydro-Electric Installations.—There are no present indications of any developments that would make future hydro-electric installations more attractive economically than those already in existence. If anything, the natural trend will be toward less economical installations. The most economical sites were developed long ago, and those that have been exploited recently have, in general, been less attractive economically than those that have preceded them. Nature created only one Niagara and that has been developed.

Trends in Transmission.—The art of transmission has been improved to a remarkable degree since the World War. Continuity standards have been improved; stability limits of alternating-current transmission lines have been extended; and the lightning hazard has been brought under control. Nevertheless, a great many difficulties in the path of completely reliable transmission have not been removed, and the costs as shown herein are still high and non-competitive with other forms of transmission at long distances. Some publicity has been given to direct-current transmission, but at present the idea is still very much in the experimental stage and its economics is totally unknown. In general, although it may be stated that improvements in transmission may be expected in the years to come, no major changes are indicated at the present time.

Trends in Distribution.—The reductions in the distribution system costs made in recent years have resulted from intensive application of increased knowledge, and from the use of engineering methods and economic principles in design. Progress has been slow, but steady. There is no reason to believe that progress in the near future will be revolutionary, but there is every reason to believe that gradual progress will eventually result in lower costs than exist at present (1937).

---

[23] "The Value of Proper Furnace Equipment to Power Plant Economy," by M. K. Drewry, Mid West Power Conference, Chicago, 1936.

Trends in Over-All Cost of Electrical Energy.—The future over-all costs of electrical energy, whether in generation or in generation plus transmission and distribution, can definitely be expected to be downward, although no rapid downward steps are indicated. It appears definite that future power requirements will be met most economically by steam plants, located at a reasonable distance from load centers and equipped with large units, with inter-connecting transmission to integrate and combine small loads and to reinforce and "back up" neighboring systems. As for steam-plant design, further progress along present lines—particularly in the expansion of the present limits of pressure and temperature, and the raising of the availability factor of both steam and generating units to make possible a minimum of duplication of facilities—will bring the optimum results. Here, however, as in other lines of endeavor, it will be necessary to rely upon "the inevitability of gradualness."

SOCIAL IMPLICATIONS OF TECHNOLOGICAL TRENDS IN THE POWER INDUSTRY

BY RALPH E. FREEMAN,[23] ESQ.

SYNOPSIS

The general effects of trends in energy generation on the level of living, unemployment, overproduction, and population distribution, are treated in this paper. A plea is made for a clear distinction between the business point of view and that of the social reformer.

The purpose of this paper is to discuss some of the economic aspects of the technical matters dealt with in the preceding papers.

To begin with, two generalizations may be drawn: First, the costs of energy generation are coming down, and in spite of many obstacles are likely to be lowered still further in the future; and, second, changes are taking place in the relative efficiency of generating energy by different methods, and the trend away from earlier methods still proceeds, moving in the direction of large inter-connected steam and hydro-electric generating plants and, to a less degree, under favorable conditions, in the direction of Diesel power.

It is hardly necessary to dwell upon what is the most obvious result of cheaper power, namely, increased economic well-being. One need only compare the standard of living of to-day with that which prevailed before the discovery of the energy latent in steam to realize the economic benefits of more efficient generation of energy. When a unit of energy is produced with less expenditure of human and material resources, the amount of consumable goods at the disposal of the community is augmented. The effect upon the individual depends, of course, upon the size of the population and the distribution of wealth; but, with no changes taking place in the number of people or in the manner in which wealth is shared among them, cheaper energy means greater material well-being for the individual members of the community.

In the minds of many people in the United States, however, the growing productive capacity of an economic machine driven by cheaper power has raised some terrifying possibilities. They fear a chronic condition of glut due to the incapacity of the markets to absorb the increased output. They believe that, largely as a result of improvements in the generation of energy, the United States is entering upon a new phase of development, another industrial revolution. They claim that, whereas once the country suffered from a scarcity of goods, to-day it is overflowing with plenty. The old economic problem was how to produce enough; the new one is how to dispose of all that can be produced.

This dread of superabundance is groundless. The scientists and engineers who are engaged in raising the efficiency of the power machine system need not be disturbed. Overproduction is an economic phenomenon, not a physical one. Overproduction is unprofitable production; surplus capacity is capacity which cannot be utilized without loss. The goods now glutting the markets of many countries would immediately vanish were they offered for sale at low enough prices. At some price or other buyers could be found for all the wheat the United States is capable of growing, and for all the output of all its steel mills running at full capacity. That this drastic procedure is not feasible is chiefly because of the relatively high prices the farmers and steel-makers have to pay for their materials, supplies, equipment, etc. Congested markets are the result of disjointed prices, and these, in turn, are attributable to unbalanced relationships between one industry and another.

---

[23] Prof., Dept. of Economics and Social Science, Mass. Inst. Tech., Cambridge, Mass.

To dispose thoroughly of the naive conception of a world that is spilling over with abundance would take much more space than is allotted to this paper. The delusion of plenty would be harmless were it not for the fact that it obscures the fundamental nature of the economic problem. It leads people to think of this problem in terms which clearly imply that a solution is to be found in an expansion of money incomes or in a contraction of the volume of goods produced. When people get the notion that depressions are attributable to under-consumption which can be avoided merely by distributing to the poor an increased supply of paper money, they are easily mobilized in support of ill-conceived currency, pension, and "social-dividend" schemes. When business troubles are regarded as the result of excess production, there is an agitation for reduction of output by drastic curtailment of working hours, by checking the introduction of technical improvements, and other restrictive measures.

Conditions may exist that call for additional media of exchange or less productive capacity in certain industries or even for a shorter work-day; but the fact that at times such measures may be beneficial does not imply that the basic cause of economic disturbance lies in a scarcity of money or in a superfluity of goods. At other times there may be too much money available or, in certain industries, the output of goods may be too small. Indeed, as a general rule, the ultimate source of disorder can be traced to unbalanced relationships between one industry and another that are quite independent of the total volume of output or of the total amount of currency in use. Overproduction, in other words, is a symptom of economic disease rather than its cause.

Another important economic result of generating energy at reduced cost is the further displacement of human labor in industry. Since the Eighteenth Century, when the invention of the steam engine enabled Man for the first time to make non-human energy work for him at his chosen time and place, human physical labor as the power supply of industry has been virtually eliminated in many fields. In other types of production, however, the elimination of human power awaits the invention of new machines to handle refractory materials and to deal with complex assemblies of parts, or it awaits the arrival of that relation between labor cost and energy cost which will make it profitable for the producer to substitute machine power. There is no doubt that a cheapening of non-human energy will hasten this substitution, especially if wages remain at their present levels or if, as seems likely, they continue to advance.

On the whole, such a development would be socially beneficial. Where mechanization is still in the half-and-half stage, where invention and research have absorbed only partly the old handicraft processes into the new energy system, a great deal of power has still to be provided by the human element. This makes the worker virtually a part of the machine. He is compelled to perform semi-automatic operations which are stupefyingly monotonous, often at a pace set by the machine which demands a nerve-wracking degree of strained concentration. When the difficulties in the way of complete automatism are overcome, the daily lives of many workmen will be relieved of much deadening drudgery.

Experience with the effects of reductions in the cost of energy generation in the past indicates that there is no need to fear a permanent addition to unemployment because of such developments. Cheaper non-human energy, although it displaces labor as the physical power supply, increases the demand for supervisory and other forms of what may be termed mental labor. Moreover, it enables men and women to leave the mechanized industries and enter occupations of the human service type, trade, finance, amusement, and various kinds of clerical and professional work. There is a real problem, of course, in the re-employment of the man thrown out of a job; there are obstacles to the movement of labor from one occupation to another which are serious, particularly in the case of highly specialized workers; but history clearly demonstrates that when a thousand men are displaced by an improvement in energy generation an additional thousand men are not thereby permanently placed on the relief rolls. A compensatory demand for labor arises from the enlarged social income made available by the reduction of power cost.

In addition to the economic problems arising from the trend toward cheaper generation of energy, there are many interesting economic implications in the changes that are taking place in the relative efficiency of generating energy by different means.

During the Eighteenth and early Nineteenth Centuries the direct application of steam energy brought about far-reaching transformations in the psychology of the worker and his relation to his employer. It resulted in a concentration of production because the increasingly complicated and expensive machines required greater capital and larger productive units; and since the machine compels men to limit themselves to certain branches of production, it resulted in greater specialization. It brought mass production that destroyed the individual character of the product and created uniformity in the wants of consumers. Mechanization resulting from steam power not only extended the period of production, introducing additional intermediate stages, but also increased the proportion of capital goods in the economic structure, and both these factors have enlarged the range of economic fluctuations. Mechanization has enhanced overhead costs relatively to variable costs, thereby introducing rigidities into the price structure which further accentuate industrial booms and depressions.

Are the recent changes in energy generation likely to affect any of these conditions? Consider, for example, the centralization of production in large plants in congested urban centers.

Steam power, if not converted into electrical energy, must be used where made. It is available chiefly, therefore, to the large manufacturing plant which produces power on a large scale; but electrical power can be distributed to points at a distance from the generating station, and made available at low cost to small producing units. Progress in electrification, therefore, may remove the advantage that steam power gives to large manufacturing units.

This applies also to the development of the Diesel engine, in which the economical size is not such as to favor the large generating unit. If cost conditions in a given industry and locality permit the profitable use of Diesel engines of relatively small capacity, small plants may be able to compete successfully with large ones. Whether such situations are now common, or whether there is a trend in this direction, is a matter for competent engineers to determine.

As to whether or not developments in energy generation will in fact lead to a producing system of small plants dispersed over the country, it is not yet possible to make a safe prediction. Although steam power was one of the influences which massed industry into urban centers, the concentration of production is not due to power considerations alone. Marketing facilities, the proximity of suitable labor and raw materials, and various other factors are important in determining the location of industrial plants. Where such factors as these constitute an important part of the cost of production, the electrical development is not likely to effect a great deal of decentralization.

In 1935, Mr. Daniel B. Creamer published the results of a study of population movements, entitled "Is Industry Decentralizing?"[34] This *Bulletin* discloses the major trends in the location of manufacturing industries in the United States from 1899 to 1933. It presents evidence of a moderate amount of decentralization—not so much a scattering of factories up and down the length of the land, but rather a spreading of industries from the great urban centers to their suburbs. Mr. Creamer indicates that, in many cases, particularly in the textile and boot and shoe industries, this movement has been due primarily to the possibility of hiring cheaper labor in new locations. On the other hand, it is to be observed that this migration of industry would have been impracticable in many instances had it not been possible to secure the necessary power in the new locations at reasonably low rates. In other words, although it is doubtful whether power costs in most industries are large enough to be a determining factor, they become of great importance in conjunction with other factors.

There is no doubt that a thoroughgoing diffusion or dispersion of industry would create another revolution in American social life, and in recent years the movement in that direction has given rise to an agitation that the Government should do something to encourage it. This agitation has been reflected in recent governmental policy. Various resettlement proposals and power projects have won support from those whose imaginations have been caught by the vision of a de-urbanized world. In many ways the ideal is attractive. There is, however, a danger that projects may be initiated that are out of harmony with fundamental economic and engineering principles, and that this will result in financial loss not only to the supporters of the new projects, but also to those enterprises with which those projects compete. Financial cost should not be the only guide in these matters; but before public subsidies are expended, careful engineering and economic investigation should be made to determine the cost of the expected social benefits.

---

[34] "Study of Population Re-Distribution," *Bulletin No. 3*, Univ. of Pennsylvania Press, 1935.

As long as the economic regime is not centrally planned and controlled, productive activities must conform in large measure to the dictates of prices and costs. To ignore the monetary signals is to invite chaos. It must be assumed that, in the main, prices are reliable guides for the organization of the national economy. It must be assumed that changes in the amount of money offered by buyers (which influence prices) reflect changes in the wants of the community and that these wants should be satisfied. It must be assumed that technical changes (which also influence prices) reflect changes in the physical cost of production and that Society should produce its goods and services with the minimum expenditure of human effort and materials, economizing those forms that are relatively scarce.

This is the method by which, in the main, the economic activities of the United States are organized. It is the regime under which the people have advanced to their present condition of wealth. Moreover, it can be demonstrated that in many instances a departure from this means of organizing the nation's productive resources has reduced the efficiency of the economic machine. The attempts of private monopolies or agencies of Government to set prices at variance with fundamental technical or demand conditions have often been followed by serious maladjustment.

Of course, it is permissible to go behind the price structure to the ultimate conditions of physical cost and human demand and inquire whether prices reflect accurately and faithfully the relative scarcity of resources and the wants of the community as a whole. Thus, it may be argued, on the technical side, that relative prices reflect the relative scarcity of the material means of production in the present and take insufficient account of the future. In the case of energy generation, it has been argued that the use of petroleum involves the depletion of resources that cannot be replaced, whereas the harnessing of falling water is open to no such objection. Should the effects of costs and prices as determined under a private profit-seeking regime, therefore, be modified, and hydro-generation of energy be subsidized in the interests of conserving natural resources? In putting such a policy into effect much caution would be required. It is hazardous to base social plans upon future technical developments which cannot be clearly foreseen.

There is also the question of the social cost of changing techniques. When one method of energy generation displaces another suddenly and over a wide field, obsolete plant is likely to be created, and men are thrown out of work. Idle men and idle machines constitute a cost that is not taken into account in the price system, but it is a cost, nevertheless. Should this social cost be mitigated by governmental action regulating the rate of technical change or imposing a financial burden on the source of disturbance? Changes in the technique of energy generation may affect wide areas of the country and large sections of the population. Should one class or one region bear the cost of technical progress? What should be done about it?

Prices reflect the demand of those who have money, but they do not accurately express the wants or desires of the community as a whole. The price of electrical energy, for example, may be too great to enable an important group of consumers to enjoy its advantages. Should the farmers be given especially low rates to permit a more extensive use of electric power on the farms? Should the Government subsidize power projects to foster agricultural development? Should power projects be constructed by the Government in agricultural regions where private enterprise finds it unprofitable to operate? Questions such as these cannot be excluded from a discussion of the economics of energy generation.

In current controversy, however, there is much confusion and evasion of issues. Lower rates may be advocated on the ground that a greater consumption will result and that enlarged output and sale will permit lower unit costs. That is an economic argument valid within the exchange-price system; but when lower rates are advocated in order to benefit certain types of consumers or to stimulate certain other industries—that is an argument that may be valid on human or social grounds but is outside the economic plane of prices and costs. In considering the problem, these two types of approach are not always kept clearly in mind. Moreover, because accurate quantitative measurement and determination is much easier on the cost-price level than on the social level, many people (scientists and engineers in particular) refuse to admit the validity of the latter. The result is that in discussing these matters there is either a confusion of the issues involved or no meeting of minds by those who participate in the controversy.

ELECTRIC POWER IN ECONOMIC PERSPECTIVE

BY B. ALDEN THRESHER,[25] ESQ.

SYNOPSIS

The bitterness of political controversy over public utilities has obscured the real determinants of the problem, which are technical and economic. The industry might be conducted successfully under any one of many types of organization, public, private, and mixed. Regulation in the United States has placed an undue emphasis on valuations of physical property quickly outmoded by obsolescence. Both the public and private sectors of the industry are seeking the same basic solution under forms which are superficially different.

The long and bitter controversy over the regulation and control of electric power has obscured certain aspects of the problem which are of abiding and fundamental importance. The issue between public and private operation, between more regulation and less regulation, between the Securities and Exchange Commission and the holding companies—in fact, the long, running fight which has accompanied the entire period of growth in this industry—is, when seen in true perspective, a mere incident in a larger development. That larger development consists of the simultaneous growth of supply and demand. On the supply side is cheap and abundant energy flexibly distributed and readily controlled. On the demand side are marked changes in industrial organization connected with the use of cheap power in industry, and even more spectacular changes in social habits as the retail consumer adjusts himself to power in the home.

The progress of the Power Industry is not so dependent on the winds of political change as many seem to think. Behind the surface controversy over forms of organization and regulation lie the real determinants of the problem—the technical limitations of economic production on the one hand, and the social and industrial nature of the demand for electric power on the other. It is easy to take sides in the current controversy, but taking sides is a mark of the pre-scientific stage of the problem. One might, for example, deplore the abuses of monopoly, detailing the long catalogue of evils that unbounded financial peace has brought upon the industry; or one might elaborate the evils of public control, and adduce examples of the "dead hand" of Government throttling private initiative. Either of these arguments would be in the current fashion; but neither would be to the point. The real issues lie deeper. They arise out of the nature of the industry itself. They will persist under public or private control, or under a mixture of the two; and they will be settled not by the choice between these rival principles, but by the economic logic of the Power Industry itself. More important than the choice between public and private operation is the choice between a stunted power industry and a well-developed one, economically adjusted to the society in which it operates.

---

[25] Associate Prof., Dept. of Economics and Social Science, and Director of Admissions, Mass. Inst. Tech., Cambridge, Mass.

Political scientists will disagree with this statement. They will argue that the issue between collectivism and individualism is fundamental and insistent. Constitutional lawyers will disagree. They will hold that the issue is between two systems of government, two opposed concepts of the tenure of rights legitimately acquired. Those in active control of the industry and immersed in its current controversies will disagree. They see their interests threatened, and few indeed are the men who can take the long view when their investments are at stake. Politicians will disagree, for the man who has to be re-elected is the last man in the world to cultivate perspective on anything.

It has often been stated that the fluctuations of the business cycle are roughly parallel in widely separated countries. Depression overtakes nations whose economic policies are widely different from each other. Similarly, when the forces of recovery are ripe, recovery appears, whether the Government policy of the moment be of the interventionist type or whether private business be left with little control.

In the development of the electric power industry throughout the world an analogous effect is evident. The industry has followed the same general cycle of technical development and consumer acceptance in all countries, although the legal, financial, and political forms under which it has developed differ widely.

In France, as in the United States, private ownership is the rule, public ownership the exception. Interestingly enough, the French power enterprises have managed to survive and attract capital without any of the so-called constitutional safeguards of which so much is made in the United States. The Parliament legislates without restraint in the matter of regulation.

In Sweden, public and private enterprise have managed to co-exist amicably. As Mr. O. C. Hormell has put it:[26]

> "While the state owns and operates an increasingly large proportion of the generating and distributing plants, the state has not taken (or been able to take) for itself any marked privileges or advantages with regard to its power development, over and above those granted to private enterprises."

In Sweden, as in Great Britain, a nation-wide distribution system yields the economies of inter-connection, and permits the public authority to control and direct power development, yet avoids the rancorous rivalry that has marred the relations between public and private agencies in the United States.

In Germany, the long-established tradition of municipal socialism in public utilities, with its roots in the Nineteenth Century, has not prevented a healthy development of private enterprises. In fact, one finds, in the post-war period, public enterprises accepting private capital and a mixed directorship.[27] In Switzerland, likewise, there is an interesting mixture of Federal, cantonal, municipal, and private ownership. The lion and the lamb have lain down together in a way that surprises Americans accustomed to the Corcyran fury of their own power controversy.

---

[26] Rept., New York State Committee on Revision of the Public Service Commissions Law, 1930, p. 468.

[27] *Loc. cit.*, p. 406.

This brief summary, which might be greatly extended, suggests that there are more fundamental economic forces at work than are contemplated in the terms of the controversy as it is usually presented. Power can be distributed successfully under a wide variety of legal and economic forms. Where there is a steady and growing demand for a service, and the technical means and the labor and capital are available, the process of production somehow gets itself organized. Whether this organization takes the form of public or private enterprise is not such a fundamental fact as one might suppose. Either form, for survival, must adapt itself to basic economic realities of the industry. In all probability, both forms will persist side by side for many years, and each will gain through the presence of the other. Frequently, the claim is made that regulation has broken down. It would be more accurate to state that the concepts on which regulation in the United States is based, have never caught up with the swift development of that technical and social complex, the "Power Industry."

The economic problem involved may be clarified by asking what characteristics in any industry facilitate a smooth and continuous adjustment of supply and demand, so that at any moment an approximation to economic equilibrium can be maintained. The following ideal conditions may be advanced as making for a smooth and prompt adjustment to economic changes:

(1) The commodity sold should be reasonably uniform and standardized.

(2) It should be sold largely to ultimate consumers, rather than to producers of other goods.

(3) It should be capable of storage.

(4) Entrance into the industry should be free and should not require a heavy investment.

(5) Abandonment of production or reduction of output should be possible without heavy loss.

(6) (A corollary of Conditions (4) and (5).) Cost should be predominantly direct, rather than of an overhead nature.

(7) The industry should be in a state of steady, but not too rapid, growth.

(8) Technical progress should not be so rapid that obsolescence becomes a serious problem.

(9) The surrounding economy should be operating with an approximately stable price level.

These conditions are obviously at variance with the actualities of the electric power industry. The commodity sold is not primarily energy, but a combination of energy, usually in small amounts, with varying amounts of readiness-to-serve, and the services of a distribution plant whose importance economically far outweighs that of the energy itself. Storage is not practicable on a major scale. The very nature of the industry prohibits freedom of enterprise in the full sense, and the fixed plant is enormous in proportion to annual gross business. Downward adjustments of output are difficult, and are likely to entail heavy loss. The tendency for overhead costs to increase, as compared with direct costs, is exceptionally marked. The rate of technical development has been so rapid as to impose a heavy burden of obsolescence on the industry.

All these departures from the theoretical ideal may be classified under two heads: First, rigidities in the market structure, centering upon the problem of overhead cost allocation, and leading to a condition of natural monopoly enforced by the technical conditions of production; and, second, dynamic elements; that is, rapid qualitative change in technique and in demand.

Some examples of the rigidity caused by the difficulty of cost allocation may be mentioned briefly. First, there is the definition of the unit or commodity sold. Most problems of rate structures involve this basic question. It may be seriously questioned whether an energy unit is an appropriate one. The rich variety of multi-part rates, the attempts to separate stand-by and readiness-to-serve elements, and customer costs and distribution costs, indicate that the commodities sold often consist chiefly of elements of access and availability.

More important still is the group of maladjustments arising out of heavy overhead costs, which, in turn, are traceable to the predominance of fixed plant in the total investment. The most obvious problem under this head is that of depreciation and operating cost. In a body of fixed plant which is undergoing rapid expansion the effect of inadequate depreciation reserves can be long postponed. As long as expansion continues, retirements continue abnormally light in proportion to total investments, and true costs may long be under-estimated. In this respect a day of reckoning is surely in store for many companies otherwise conservatively managed.

It is in the matter of capital charges and rate of return that controversy has been most acute. The history of public utility valuation contains a lesson which is important not only for the power industries, but for many others as well. In this controversy both sides have taken the line of expediency and immediate self-interest, rather than that of long-range wisdom.

In 1898, when the case of Smith *v.* Ames was decided at the end of two decades of falling prices, consumers, represented by William Jennings Bryan, argued that valuation of utility property should follow reproduction cost. This, under the circumstances, led, of course, to a lower rate base. Producers (in that instance, the railroad companies) clung tenaciously to the higher original cost of construction, as representing their idea of justice.

In the long upward swing of the price level to 1920 these positions were sharply reversed. The growing utility companies went on record in great detail as favoring reproduction cost, both in practice and in theory. It came to be assumed almost as a law of Nature (so short is human memory) that a reproduction-cost rate base is always higher than the original cost.

Another complete reversal of positions might, therefore, have been expected in the price liquidation in the years following 1930. This reversal, however, was only partial and incomplete. The constitutional guaranties which seemed to hedge the reproduction-cost concept, gave to the producing interests a different kind of advantage from that arising from mere price changes.

In an industry in which costs are falling rapidly, any device that delays a normal price readjustment may be expected to offer great temporary advantage to producers. The constitutional guaranty with which the Supreme Court has hedged property devoted to public use supplied just such a device. Public clamor was partly quieted by partial rate reduction, but largely resisted by resort to the Courts. A fair return on the valuation was increased by hypothetical calculations, which assumed reproduction, at great expense, of plant which no one could logically wish to reproduce. This is not to attack the motives of the power companies. They acted in good faith in seeking legitimately an advantage that was legally and morally theirs. Their attorneys were not hypocritical in pressing for the last penny. More accurately, they were honest, but short-sighted.

As the matter has turned out, theirs was a Pyrrhic victory. The rate reductions, which were resisted so strenuously, have mostly been conceded, not in deference to any legal right of the consuming interest, but rather out of sheer expediency. The technical and economic situation in the industry has swept aside a body of legal principle. It is not that the legal principle was unjust or reactionary; in fact, it represented an honest effort by able men to do justice to all parties in a complex situation. The error lay in the failure to take account of the economic effect of technical progress in an industry in which technical progress has rushed ahead by leaps and bounds. The year 1930 found the power companies strongly entrenched in an unassailable legal position, honestly won. The year 1936 found them conceding more ground than they had gained; and they were doing so in response to economic and technological forces stronger than any body of legal rights.

This aspect of the problem must be left for a moment to consider other types of rigidity that distort the free play of market forces. The Power Industry, in common with transportation, is a proper field for class price, or, more properly, price discrimination. It should be understood that this is not a term of disparagement. Discrimination may be defined as "differences of price not attributable to differences in cost."

Discrimination is possible: (1) When there exists a monopoly, or at least a sufficient approach to monopoly to prevent competitors from breaking down a system of class prices; and (2) when the commodity sold is not susceptible of storage and resale (railroad freight rates are a classic example, and rate differences between main classes of electric power loads illustrate the same principle). What the public often fails to appreciate is that such discrimination actually benefits not merely the class of customers serving the low rates, but even the persons who apparently are discriminated against as well. In so far as a low rate brings in business not otherwise obtainable, it allows the burden of overhead to be distributed more widely, and hence prevents the high-rate business from carrying an even higher rate.

Finally, as a typical result of heavy overhead cost, one finds the phenomena of diversity and inter-connection, which have played a large part in power development. Here, again, the situation is completely at variance with that which prevails in the sale of most commodities. It is necessary to reckon not merely with the normal economies of large-scale production, but with those differences in timing that make it possible to improve the central station load factor by connecting loads of different characteristics. Both the class-price principle and the diversity principle make for a degree of economic solidarity among power customers that is not equalled in any other industry. The price Jones pays for a pair of shoes or a set of tires depends upon how many other people are willing to buy shoes or tires, but the price which Jones pays for electric energy depends not merely upon the number of other customers, but upon what time of day they use their power. Jones, furthermore, may actually benefit by having somebody else buy power cheaper than he does—although Jones would probably never be convinced of this, even if all the rate experts and economists in the world should try to demonstrate it to him.

The peculiar economies of load diversity, over and above those of mere large-scale generation of power, have led to regional inter-connection by several different approaches. It early became apparent that diversity was advantageous within a single community. To bring it about also between communities and regions has been one of the major objectives of consolidations and holding company developments since before the World War. The same logic underlies private contractual interchange agreements like the Connecticut Valley Power Exchange. The British "Grid" provides still another variant, with a public inter-connection system interposed between private power producers and retail distribution systems of which some are public and some private. The Grid thus serves as a stimulant to unified development of a national system, but leaves that system predominantly in private hands. It serves also as a regulative device by interposing the public authority as a middle-man, instead of, as in the United States, either a competitor or a policeman. Still another variant is found in the regional projects under wholly public auspices, like the Tennessee Valley Authority.

It has been well said that the human mind recognizes differences more easily than it perceives similarities. The four devices just listed are a case in point. Their relative merits are disputed so strongly that the fact that they are all expressions of a common principle is forgotten. What is really important is to get this principle recognized and utilized to the fullest extent; which device is used makes little difference.

The characteristics thus far mentioned are, so to speak, permanent differences which earmark the Power Industry as distinct from most others. Even more significant, however, is the dynamic phenomenon of rapid change, both in technique and utilization. In an industry where technical development is rapid, and utilization both by industry and the consumer is developing with equal rapidity, economic forces making for a normal equilibrium work too slowly. Costs are falling over the long period, but only with the aid of large new investments of capital. Demand is growing, but it grows faster where the desire for secure profit is tempered by willingness to postpone returns, so as to attract further business. It will be argued, however, that many other industries are in a similar condition of rapid change. Why should the Power Industry be singled out as being affected to an extraordinary degree by accelerated technical progress and by changes in the response of consumers?

The answer seems to lie in the presence of public regulation. The concepts that make up the accepted scheme of regulation in the United States are by their very nature static. The legal theory of an adequate return on the fair value of the investment is valid and sound for an industry in a stable condition. It provides, in effect, that "every tub shall stand on its own bottom"; but the moving equilibrium of a runner in rapid motion is a different phenomenon from that of a man standing still. The accepted theory laid down by the Courts finds support in the instinctive logic and sense of justice of any one who takes the trouble to reason out the problem. However, on every hand, it is seen how the technical and economic changes that keep the industry in constant ferment have already set these theories at naught.

The explanation is to be found in what has been called "the fallacy of misplaced concreteness." The Courts have put their trust in tangible equipment—that is, in property in the physical sense. It is a natural error, seeing how large, impressive, and indispensable is the physical plant necessary in this industry; but the error consists in not recognizing that the physical plant is only the passing embodiment of a technique that is undergoing rapid development. The concept of value envisaged by the Courts is of a property inherent in tangible objects; hence, the elaborate engineering appraisals that support "physical" valuations.

If there is one contribution that the economist should make above all others to the public utility problem, it is to demonstrate that value is not an inherent property dependent upon the dimensions or specifications of a tangible object, but an economic, hence partly psychological, phenomenon dependent upon conditions of use and demand. Obsolescence is not a physical but an economic process. It follows that in a situation where productive methods and productive technique are rapidly changing and improving, and where the nature of the demand is shifting, any attempt to set a value on a piece of property solely as a function of the physical nature of that property is doomed to failure. It is the misfortune of the utility industry that something as transitory and changing as its current technical methods must be embodied in fixed plant which is so permanent and expensive. This plant soon becomes a lifeless shell, when changes in method require a shift in the type of equipment.

The legal theories of regulation have never succeeded in grappling with this problem. The short-run result of such a situation has been to benefit the utility companies. Once rates are set, it has usually been possible to cut costs sufficiently that a considerable addition is made to the rate of return nominally earned on a given investment. Were this not true, all incentive would long since have been removed from the industry. The engineer can be thanked for thwarting the regulator and allowing the industry to adjust itself to the facts of social and economic change.

It seems fair to conclude that this situation is largely responsible for the contemporary emphasis on Federal power projects. It is shallow to regard the Federal program as merely punitive, or as evoked by the misdeeds and abuses of the power companies. It is true that there has been widespread exploitation and abuse, and, in this respect, the Power Industry has accurately followed the pattern set by the railroads a generation earlier. A wide margin of waste, misapplication of funds, and general inefficiency seem to be the normal price of a rapid expansion process. The phenomenal speed and effectiveness with which the railroad and power networks have overspread the continent have been offset by a heavy penalty of frenzied finance and exploitation. Similarly, the war effort of 1917 and the more recent effort to apply Federal funds to large-scale projects both led to colossal economic waste, although some net advantage appears in both cases. All this, although it seems important in the light of the political situation of 1937, will be regarded with a calm and tolerant eye by the economic historian.

It is more accurate, therefore, to regard the Federal power program, whatever its merits or defects, as a response to a long-standing maladjustment, not as a punishment meted out to malefactors. The machinery of State regulation is often said to have "broken down." More strictly speaking, it has always lagged behind the situation with which it strove to grapple. This was true even in the days of local power units, because of the rapid rate of technical change. It is doubly true now that regional inter-connections extend over areas beyond the jurisdiction of regulative authorities.

Are the people then to be content with the imposition of "yard-stick" projects that are manifestly unfair? Is the ineptness of public regulation in the past to be an excuse for unfair competition in the future? It is doubtful whether the problem can ever be solved merely by territorial division and rate adjustments between public and private enterprise. Such a solution, although desirable, is too much to hope for. In practice, some working basis will be arrived at because the demand is still expanding so rapidly as to permit, within a relatively short time, utilization of both private and public facilities without seriously overcrowding the field. As always before in the economic history of the United States, progressive expansion should provide a correction for miscalculations and errors—both those of financial exploitation by private interests, and the equally glaring ones of public policy.

A time will come, however, when economic maturity will overtake the industry. Mistakes will then be more costly because growth will be slower. When that day comes, a lesson may be learned from countries like Switzerland and Sweden. One may hope it will by then be apparent that a public temper which inclines toward moderation and co-operation is indispensable for the full development of a technical and social complex like the Power Industry. The engineer holds the key to continued progress, but unless such a temper prevails, his labors will be in vain.

DISCUSSION

W. S. FINLAY, JR.,[28] ESQ. (by letter).—In any discussion of the economic aspects of energy generation, one can distinguish at least two levels—the level of pecuniary analysis and the level of social or human analysis. However, one is scarcely justified in so limiting the range of vital factors dominating the life, opportunity, and progress of the power industry.

For instance, there is a certain type of professional mind which has been identified with much that has made the industry what it is, and whose contributions are of essential importance, but which is motivated solely by the compelling thought of producing something of a highly technical order, without regard to the bearing their product may have on economic, social, or human aspects. That sort of mind can be classified as similar in its make-up to that of an artist who endeavors to reflect his ideals on the canvas upon which he paints.

Such a contribution is certainly worthy of consideration as occupying a third level. True, economics may enter into work on such a level, but history shows that it is frequently only in the last stages of development that the vision of an inventor's mind is forced into a mould that relates itself to economics. The incandescent lamp was long in existence before it was given commercial value by Edison and adapted by him to human use and service.

It may thus be possible to isolate within other levels some of the vast range of activities that compose the power industry, but is not the isolation of components working in a contrary direction to the purpose of a symposium? Is not such a purpose that of discovering, if possible, a reason for the theory that the general activities of the power industry, involved in the generation and use of electricity, cannot be isolated one from the other in levels, or in any other way? Is it not a fact that in any industry the viewpoint of one who would appraise it must be that which embraces it as a harmonious whole of men, machinery, money, materials, and more?

With the background of such an argument, the writer assumes, for purposes of discussion, that this particular form of industrial activity is indivisible into any component parts. There is a constant necessity for "give and take" among its pecuniary, social, sheerly technical, and political components. This Symposium supplies a background in indicating only a few of these interrelationships. To bind the parts together into a harmonious whole, and in a manner thoroughly satisfactory to all who have interested themselves therein, particularly in these latter days, apparently calls for a master mind beyond any yet revealed. At least, no one in the United States in whom students of the problem might have implicit confidence has supplied anything like an answer—anything that might direct the trends of effort and research, governmental or industrial, toward a single, ultimate, and ideal objective. One is impressed rather with a present tendency to tear apart in every direction—the belief on the one hand that the object of governmental authority is to destroy, and on the other hand that it supplies the only means by which to advance.

---

[28] American Water Works & Electric Co., New York, N. Y.

Concentrating Objectives.—The titles of the papers in this Symposium typify in a small way the diversity of interests that motivate many minds whose theoretical objective is that of a common purpose. Long before the use of electric energy became a factor of importance in living, Man struggled to maintain life, to accumulate wealth, and thereby to promote the comfort of living. As incidentals thereto he adapted machinery to his purposes, he endeavored to transform energy from one form to another in aid of such purposes, he regimented other men in his service and, in turn, adapted his own activities in relationship with those of other individuals, groups, and nations. The whole created a civilization. Electricity entered, became a force, an element of value, a service, a means for creating wealth, and grew almost over night into an element of major economic importance, theoretically affecting human welfare not only here or there but almost universally. Certainly, so far as the United States is concerned, it has been elevated to a pedestal of national importance. Whether or not such importance is exaggerated is a matter open to discussion. Unquestionably, from the angles of politics and publicity, it is occupying, at present, rather a top position. Perhaps it is a proper part of this discussion to inject the throught that this position of importance has been exaggerated to a degree for which there exists no warrant, social or economic.

Near the beginning of his paper, Mr. Freeman states: "It is hardly necessary to dwell upon what is the most obvious result of cheaper power, namely, increased well-being." In that sentence he places his finger upon the theoretical yeast that has inflated an enormous loaf of political aspirations and popular theories that at best have an uncertain background of factual warrant. If it were not for the popular idea that an unlimited amount of electricity is a sort of Aladdin's lamp for the mere rubbing of which any individual can find relief from labor, from care, from expenditure, there would be little popular support to the political plaything that electricity has come to be. The importance and value of Mr. Freeman's key sentence depend wholly upon whether electric power can be cheap, and, thereafter, upon what contribution electric power can make to economic well-being. Without pursuing the theory to a conclusion, certain facts drawn in part from the other papers of the Symposium can be introduced to indicate the doubt of much of the social theory that supplies the background for such a key sentence. It is the writer's purpose to examine this factual background and to the extent to which the key sentence is affected by such an examination, the entire discussion is affected.

The writer may be one of a minority who holds a definite belief that the social importance of what is termed "cheap power" has been greatly exaggerated—in fact, exaggerated to such a regrettable extent as to create a demand for something that cannot be supplied. For this reason, there is bound to result deep disappointment upon the part of many, with the result that the social aspects of the general problem will take the form of resentment against those who made promises. For instance, were one honestly to examine into the net social effect of electricity as measured by the distribution of population, it might be found to be rather minor except as it is affected by and related to improvements in forms of transportation facilities.

The generation of power in bulk in certain favorably located centers reflects only a certain and peculiar set of conditions. Mr. Sporn emphasizes the economic limitations imposed upon power distribution from certain centers by his comparisons to the cost of transporting fuel for the generation of such power. Certain limited hydro-electric sources of power create special situations; but others too often tend to concentrate population in industrial areas about a source of energy, thus contributing to the difficulties resulting from such a concentration rather than supplying a solution to the problem.

To certain realistic minds, the social effects and value of electric energy supplied from a central source and distributed to the farm and rural home are distinctly uncertain and untried. To the actual costs of such service must be added the cost of electrical equipment, the fixed charges on which almost unquestionably exceed materially the actual price of electric current. The ability of the farm to carry the burden of cost will depend directly upon its producing capacity and earning ability in ways that are wholly unrelated to the availability of central station electricity to the farm.

Carrying the thought a bit further, the farmer may actually be impoverished by his attempt to carry the burden of the actual cost of such electricity. In other words, he might better continue the use of other and cheaper forms of energy plus possibly such an adjunct as an oil-engine generator set for home lighting and other minor service.

As relating simply to its social effect and value, of course, electricity in the home has a certain place of importance as a substitute for gas and oil, but there is nothing in that importance which calls for a complete re-organization of the service background of electricity as a commodity. In other words, there is no peculiar social value in service and power generated by a publicly owned central station that is not inherent in similar service and power supplied by a privately financed and operated source. In fact, the development and progress of any form of public service, be it electricity, transportation, or any thing else, have been far greater under the spur of private initiative than under governmental ownership and direction. Practically, every feature of value in power generation and service in nearly every publicly owned and operated plant in the United States had its origin under the stimulation of private investment and initiative.

In brief, the writer can find no warrant for attaching extraordinary social values to the manner in which electricity is generated and used. Yet these values have been seized upon as the basis for wholly illogical argument and masses of propaganda designed to transfer the industry in part and eventually as a whole to public ownership and operation. History has proved that under public regulation and private management, transportation plays as great a part as power—if not, indeed, a greater part—in the social life of the nation. Again, the production and distribution of food have equal, if not greater, social significance. Everything that relates to life, to ease and comfort, in general, has no more and no less social significance, and no one factor should be singled out for special treatment, control, or direction.

This general concept has been recognized for years by the man who has specialized in electricity and electrical service—that is, by the power producer, who relates every phase of his service, from the financing stage onward, to a consideration of its proper use at the point of consumption. In brief, he is the privately owned power industry of to-day.

The Technical Aspects of the Power Problem.—The various papers which have set forth individually the technical engineering features of the problem are inter-related and might almost have been combined in a unified whole. Progress in the art of power generation, as described by Mr. Orrok, is a magnificent record of achievement upon the part of a record-making and record-breaking industry; and is clearly indicative of extraordinary possibilities for the future, provided nothing is done to stifle private initiative and inventive genius. Mr. Rogers' paper illustrates the extent to which specialization in one field of power generation tends to contribute to a well-organized and forward moving whole. As an addendum, a paper might have been prepared, setting forth the extraordinarily complicated combination of the various forms of engineering comprised in a modern steam station. Thereto might have been added the complex problems of an electrical and economic type that the engineer is called upon to organize in making up a properly balanced power generating, transmitting, and distributing system.

Economics in Engineering, Generation, and Distribution of Power.—Mr. Justin has touched briefly upon some of the "high spots" of the economics of power transmission and distribution. The brevity of his presentation is possibly responsible for its apparently being rather more idealistic than practical in its concept. For instance, inter-connection of systems with the objective in mind of securing some advantage of an economic character is, and for years has been, merely a part of the ordinary day's work of the electric power industrialist. The value of these inter-connections may be based upon anything from economies in financing to insuring reliability of service to some remote customer. The history of the industry has been notable for the extent to which advantage has been taken by the various industrial units comprising the industry, of co-operative action to procure results of maximum economic interest, not only—as has been frequently over-emphasized—that accruing to the stockholder, but to the user, whether a large industry or an individual whose interest is limited to the service in his home. This fact is not as generally appreciated as it should be, and those who are prompted by a motive which might result in some form of prestige have deliberately endeavored to obscure the fact. On its part, the power industry has been backward in advertising.

The best evidence of the fact that the power industry has taken advantage to an extraordinary degree of every opportunity to cheapen and stabilize the service is the rate of progress that it has made in a very brief span of time. No industry has made, or is making, a like rate of progress.

Mr. Sporn's exceedingly well-written paper is based upon facts and figures rather than on theory. However, he cannot resist the temptation to which all engineers are subject, namely, to do a bit of forecasting. He refers in particular to probable trends of various departments of service within the industry and of economics relating particularly to production with the consequent effects on costs of the service.

There is this in favor of the reasonableness of Mr. Sporn's forecasts: The power industry of to-day is the result of years of intensive combined effort on the part of those engaged therein, which is in no way limited to engineering alone but involves everything that goes to make up a progressive industrial service—financing, sales methods and psychology, social effects, technical engineering, the perfecting of mechanical processes, etc. Unlike the average industry, it is not limited in its advancement by the advantage gained by individual units from the development of patented or special processes. Its extraordinary progress has in the main been due to the readiness—the actual anxiety—of those engaged in it to exchange ideas and information as to every phase of performance or detail of service.

This type of progress inclines one to the opinion that little or nothing has been overlooked in the way of developments that have contributed to the success of the industry, its efficiency, or performance. There are no secrets—no developments that are not fully known or made use of if needed or wanted. The industry is one which has led and directed the manufacturer in his supply of its tools of service. True, the manufacturer in his own laboratories has devised many a type of equipment of value to the industry; but the greatest laboratory has been the field of service—and the directors in that laboratory have been the power industrialists themselves, with the manufacturer as a most co-operative and able partner.

In the light of the foregoing, it is rather difficult to disassociate one's ideas as to future trends from what has been and is being accomplished. It would seem illogical to think that any sudden discovery will eliminate the great waste of heat energy that now attends the generation of electricity in steam plants; hence, one's ideas as to the obsolescence of generating machinery are developed rather in terms of something progressive than in the direction of something revolutionary that might suddenly destroy vast values in equipment, transmission lines, etc.

Nevertheless, there are those who envision the possibilities of new and wholly unknown ways of energy transformation and concentration adaptable to the service of mankind; however, if there is any precedent in history, it is that such changes can only be gradual and as the result of persistent, progressive, time-taking invention and research.

If that theory as to the future of the industry is correct, there is every reason for maintaining it as a wide open field of opportunity for private initiative and inventive genius, rather than permitting it to become a political plaything, stifled by bureaucratic control and direction. Responsibility for progress in the power industry, as in every other industry, in a democracy such as that of the United States, must rest in the application of individual effort spurred by the profit and success motive, and not in the benevolent paternalism of the political appointee or aspirant. The economics of power production still remain essentially a matter of endeavor upon the part of those who would apply themselves to intensive specialization, devoting their span of life thereto. It is not and cannot be the hit-or-miss achievement of the dilettante in politics, sociology, or reform for reform's sake.

R. M. RIEGEL,[29] M. AM. SOC. C. E. (by letter).—The advances in the art of turbine design and manufacture which have been described by Mr. Rogers, particularly those in the field of the propeller turbine, have been very important. Special consideration should be given to the extensive use of the manufacturers' laboratories, in which so many of these advances have originated. The staffs of these laboratories conduct their work with care and scientific exactness, and their product has been extremely valuable. However, the results of model tests must be verified by experience with the prototypes, and occasionally phenomena occur in the full-sized units which have been too obscure to be observed in the small models. In studying the performance of full-sized units, the power engineer functions in furtherance of the research in the manufacturer's laboratory. Other important research has been performed by interests which purchase equipment.

The use of large propeller units is comparatively new, and some facts still remain to be learned about their characteristics. The ways in which the power engineer will contribute to the art is illustrated by a case of the TVA. The two units at the Pickwick Landing Dam were designed with a horizontal splitter in the draft-tube. The two units at Wheeler Dam have no such splitter. The units at the two plants are quite comparable in size, head, and discharge, the Pickwick units being a little larger. The splitter is a difficult and expensive detail of construction in units of this size and should not be used unless it is advantageous. From the comparative performance in these two plants the TVA and the Engineering Profession will have evidence to determine its merits.

Another investigation of the TVA indicated that it was feasible to tip upward the horizontal leg of the draft-tube in units of this kind to a degree which previously had not been deemed feasible, and the specifications for the Pickwick units required that a high slope be used. In the dams of the TVA, the large propeller units require considerable rock excavation to accommodate the deep draft-tubes, and the tipping up of the horizontal leg represents a real saving in construction cost and a widening of the field of this type.

Another investigation in the laboratories of the TVA is that of a head-increasing device which may be applied to the dams on the Tennessee River. Head increasers have been developed by a number of engineers, including Tefft and Thurlow; and it may be that the proposed device can be worked out to widen the field of use of such appurtenances. It may be noted that these devices have been developed outside the manufacturers' laboratories.

The art of hydraulic generation has been advanced, furthermore, by the development in recent years of various accessories which contribute to safe and economical operation—improvements in governors, penstocks, trash rakes, gates, and similar devices. One noteworthy contribution is the "paradox gate" developed by the U. S. Bureau of Reclamation as a reserve valve for the needle-valves at Boulder Dam.[30] A modification of this type has been used for the entrance gates to the penstocks at Norris Dam. These gates, 16.5 ft by 28.5 ft in opening, are of heavy steel, and ride on caterpillar trains in a manner somewhat similar to the well-known Broome design. The seating device, however, is radically different, the gate being seated by a horizontal movement after it has been lowered into its proper position. These gates were installed in 1936, and are apparently operating satisfactorily.

[30] *Mechanical Engineering*, October, 1934.

In conclusion, it is worth while to note that co-operation between manufacturers and purchasers' engineers has led to numerous improvements in the past. Such continued co-operation will solve the problems of the future.

RALPH BENNETT,[31] M. AM. SOC. C. E. (by letter).—It is certainly true that the efficiency of power production must increase rather slowly in the future. The great advances have already been made. Only those refinements which come with detail study of specific cases and the use of more complicated equipment are left.

One of these refinements is provision for more efficiently carrying peak loads on plants especially designed for the economical delivery of power on a very low load factor. This does not mean merely improvement in direct generating efficiency to carry short peaks. It may mean an artificial time distribution of the load within the system generating plants, so that the total power sold will have the lowest cost in fuel and labor and in capital invested.

To some extent power plants having short intermittent peaks at close intervals can store heat to cover these peaks in heat accumulators. Electricity was once stored, for peak use, on central station networks in lead storage batteries; but other methods of carrying the peak have superseded the storage battery, except in the case of small isolated plants. In some countries, as Mr. Justin has stated, the use of off-peak power to pump water to high-level storages for rapid release through turbines during the station's peak, is well established. Thus, the external peak is met through a redistribution of station load within the system, fuel efficiency being sacrificed in favor of a lower total power cost.

In the typical pumped-storage plant, water is drawn from a convenient stream and returned to it after use. The reservoir is of small size. The up flow and the down flow of water are frequently through the same pipe, and the pump and the recovery turbine are commonly connected to an electrical unit which is run as either a motor or a generator. This plant is efficient under only a very limited range of conditions, but the energy thus recovered as peak power is very much more valuable than the off-peak power used in pumping the water. It is possible to recover about two-thirds of the power used.

The profitable investment in such a plant is much more than is permissible in a fuel-burning plant, since the rent of the money invested is almost the entire cost. The allowable investment may even be greater than the cost of a distant water power and a peak-load transmission therefrom, because the storage recovery plant, being closer to the point of use, will have lower transmission losses and greater reliability.

The pumped-storage peak-power plant, split into separate pumping and recovery plants connected by a high-level conduit and storage reservoir, can be used to carry a water conduit over a mountain range instead of around it or through a long tunnel beneath it. Many cities import their water through such conduits and, in many cases, the water system can be easily arranged for pumped-transit power recovery. The higher the lift the less the percentage value of the fixed losses and the greater the percentage of the pumping power recovered. If the mountain range is high and a high-level summit storage is available the system as a whole can be very efficient.

---

[31] Cons. Engr., Los Angeles, Calif.

However, the conduit line used for peak-power recovery will differ materially from the classical constant-flow low-level conduits as now designed. It will need a re-arrangement of petty storages and of pumping plants such that the long conduit can flow continuously. The pumps will run on a 15 to 20-hr schedule, and the regeneration plant will make its entire recovery in only 4 to 6 hr.

If the system is operated on a day-to-day basis, the terminal and summit reservoirs need still be large enough only to impound the flow during its manipulation for peak-power delivery. However, if the summit reservoir can be large, and the terminal reservoir can be proportioned for seasonal as well as daily variations, the value of the pumped-transit system will be immeasurably enhanced. In such a system lush supplies of water and seasonal excesses of power may be combined to pump available water to the summit reservoir with secondary power and thus provide potential peak power and water for a long time ahead, independent of the fluctuating rates of the stream or of primary power production.

The use of the incoming water for power production is quite compatible with the total rate of water flow required by the city. A population unit of 5 000 will use 1 cu ft per sec of water (continuous flow), and will absorb the output of a 1 250-kw power plant.

Among the cities where this type of project would appear to be of value, four may be singled out for special mention. The situations at San Francisco, Santa Barbara, and San Diego, Calif., and at Denver, Colo., are strikingly similar. In each case, an imported water supply encounters a high mountain range close to its destination. Long low-level tunnels can be driven through these mountains at great expense, or pump-fed conduits can be carried over them and through summit reservoirs and peak-power recovery plants at relatively low cost. In each case the intervening mountains are high and the total lift correspondingly great. Such a situation is advantageous in a pumped-

TABLE 5.—POSSIBLE ENERGY RECOVERY FROM PROPOSED SAN DIEGO, CALIF., WATER SUPPLY

Item	TYPE OF ROUTE	
	Summit lift, no tunnels	Low-level conduit, with 25-mile tunnel
Lift, in feet	4 000	1 100
Conduit loss, in feet	100	120
Delivery head, in feet	550	550
Net regeneration head, in feet	3 350	430
Gross recovery, percentage	83.7	39
Efficiency of combined plants, percentage	76	76
Net recovery, percentage	63.61	29.64

transit system, because the fixed losses (such as conduit friction, entry head, reservoir fluctuation, and terminal reservoir elevation) are independent of the lift. This point is illustrated in Table 5, in which the power possibilities of a low-level and a high-level route for the proposed San Diego water supply are compared.

In fact, an almost perfect example of the possible advantage of such a system is supplied by the proposed importation of Colorado River water into the City of San Diego across a high mountain range, on which numerous high-level reservoirs are already in use. The generalized profile across the Coast Range (Fig. 36) illustrates the facility with which this particular diversion can be adapted to pumped-storage transit.

Steam plants in San Diego are the primary source of power. The most distant regeneration plant would be only 40 miles east of the city; and the closest, only 15 miles. Power for the large pumps would be carried by the same transmission line, and for a maximum distance of 60 miles. Other advantages include the large high-level reservoirs already in use along the proposed conduit line, and the large low-level storage and distribution reservoir at the city's edge.

Elaborate calculations covering the allowable cost and probable kilowatt and kilowatt-hour outputs of a pumped-storage plant considered as a peak load plant for a large system are contained in a discussion[32] by A. H. Markwart, M. Am. Soc. C. E. His conclusions are based on a particular, but perhaps representative, set of conditions. Under a condition of practical balance between off-peak pumping and peak-power release, from 13 to 20% of the system energy can be used for pumping. The regeneration plant would probably have a load factor of only 10 to 18%, and would generate only 8 to 12% of the total energy delivered to the system. Yet the peak which could be carried would be 30 to 50% of the system peak.

FIG. 36.—PROFILE OF PROPOSED SAN DIEGO, CALIF., WATER SUPPLY CONDUIT, SHOWING POTENTIALITIES FOR POWER RECOVERY

Under the conditions considered by Mr. Markwart, a pumped-storage plant costing from $120 to $150 per kw, may be economically feasible. However, with pumped-transit storage, part of the money saved on conduit tunnels can be properly applied to additional plant; and although the total machinery cost may be larger, the return on the money invested in the combined water-transit and peak-power system may be much greater than the net earnings of separate plants to perform the same duties.

---

[32] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), pp. 911–932.

In conclusion, it may be stated that it is possible to design a water supply system, using pumped transit and summit storage with retarded regeneration, such that intervening heights may be made to decrease the first cost of the water and power system and to increase its earnings. In general, the higher the lift, the greater will be the net recovery; and the shorter the regeneration time, the greater will be the net earning.

J. M. Mousson,[33] Esq. (by letter).—The paper presented by Mr. Rogers gives an excellent review of the progress made in hydro-electric generating equipment. Since it is often widely believed that a stage of stagnation in development of hydraulic prime movers has been reached, it is gratifying to see that Mr. Rogers points out various fields in which further improvements are yet to be expected.

He mentions, for example, the ever-increasing heads under which fixed-blade propeller and Kaplan turbines are being installed, and refers particularly to the Shannon River development, in Ireland, where a Kaplan unit is operating under a head of 106 ft. It is interesting to note that, in 1937, the Electricity Supply Board of Ireland (Dublin), decided to install Kaplan turbines at the new Liffey Power Plant, where a head of more than 130 ft will be utilized.

In the field of pump-turbine units substantial progress has been made. Although Mr. Rogers refers only to laboratory studies with modified high- and medium-head Francis-type runners, an actual installation of a low-head pump-turbine unit was completed early in 1933 at the Baldeney Power Development, on the Ruhr River, in Germany.[34] The unit is operating under a maximum head of about 32.5 ft. Its design was based on laboratory studies of a modified 5-bladed Kaplan runner with fixed guide-vanes. The runner is coupled directly to a 50-cycle alternating-current asynchronous machine operating at 255 and 326 rpm when generating and running as a motor, respectively. Although capacities and size are relatively small (power output, 1 100 kw; power input, 1 300 kw; runner diameter, 59 in.), this installation seems important as a pioneer in the low-head field. The maximum efficiencies reported for turbine and pump operation, based on acceptance tests, are 90% and 78%, respectively. In view of the fact that for the water measurements propeller current meters of only one type (25 cm in pitch) were used, which even under practically ideal field conditions under-register by an appreciable amount, the foregoing prototype efficiencies should, perhaps, be corrected to 88 and 80 per cent. There is little doubt that the average maximum efficiency of the pump-turbine designs referred to by Mr. Rogers, based on a modified Francis runner, may be superior, keeping in mind that Mr. Rogers' results (see Fig. 21) were obtained on a 16-in. model and that an appreciable step-up in efficiency for the Francis type, pump-turbine may be expected. Aside from possible improvements in the Kaplan type, however, it should be noted that in spite of the lower average of the maximum efficiencies of the Kaplan turbine-pump installation referred to, better over-all efficiency may perhaps be achieved with this type of design, if the unit has to generate at part load over long periods of seasonal low-river stage, as at the Baldeney Plant.

[33] Hydr. Engr., Safe Harbor Water Power Corp., Baltimore, Md.

[34] "Die Turbinenpumpe in Stauwerk Baldeney" ("The Turbine-Pump at the Baldeney Power Plant"), by O. Spetzler, *Zeitscrift* des Vereines Deutscher Ingenieure, Vol. 78, No. 41, October 13, 1934, pp. 1183 to 1188.

In addition to the mechanical improvements referred to by Mr. Rogers, mention may be made of the possibility of injecting air into low-head propeller-type units to reduce vibration at high-gate opening. For instance, at the Safe Harbor Plant, Safe Harbor, Pa., vibration alone was the determining factor for the gate limit under normal operating conditions. Because of the hazard involved, even short periods of over-load had to be avoided. Air injection through the head cover proved so successful in reducing vibration that more than 1 000 kw per unit, or more than 6 000 kw for the entire station, were gained in output by stepping up the gate limit without increasing the vibration above the previous intensity registered at the lower gate limit and no air injection. Air injection of 125 cu ft per min through the head cover under high loads is now a standard operating procedure at Safe Harbor.

Air injection may be used in the future not only to improve operating characteristics, but to provide a cushioning medium to render cavitation ineffective. With ever-increasing heads for propeller-type turbines, a point may be reached where even the best stainless alloy steels will no longer resist the attack from severe local cavitation. If air injection for this purpose is to be economically feasible, however, research and model tests will be essential, because with the large volume of air required it is necessary to make the injection in such manner that the major part of the air will find its way to the particular location desired.

Ben C. Sprague,[35] **Esq.** (by letter).—In evaluating the saving resulting from the reduction of new generating-capacity requirements accomplished by inter-connection of power supply systems, Mr. Justin assumes this saving to be equal to the total fixed charges and residual operating expenses in connection with the generating capacity additions that are avoided. Actually, the addition of new generating capacity to a power system results in very appreciable operating savings, allowance for which gives a net cost of providing additional generating capacity of appreciably less than the additional fixed expense involved. These savings are obtained by operating the new generating capacity to carry the base part of the system load, replacing a similar amount of capacity which otherwise would have been operated at or near the top of the load, and which normally would have a much higher operating cost than the new generating capacity. For example, if the new generating capacity has a coal rate of 1.0 lb per kw-hr and can be operated 7 000 hr per yr to replace capacity having an average coal rate of 1.7 lb per kw-hr, an annual saving of 4 900 lb of coal—which at $4.00 per ton would amount to $9.80—would be realized per kilowatt of new capacity added. Based upon a new capacity cost of $130 per kw and a fixed charge rate of 14%, the operating saving would amount to 54% of the annual fixed charges of $18.20.

---

[35] Engr., West Penn Power Co., Pittsburgh, Pa.

As a result of the continuous improvement that has been made in power-station design throughout the past, the saving in operating cost has always been a factor to reckon with in determining the annual cost of providing additional generating capacity. This factor has had an appreciable bearing upon the economy of utilizing hydro power for carrying the peak of the system load. Because of the very low annual load factor of the load peak to which hydro power might be applied, the low operating costs obtained with new steam capacity, *per se*, have had little effect on the relative economy of steam or water-power capacity additions. Rather, it is the lower production cost of the new steam capacity, as compared with that of the capacity it could replace, which is so important a factor in steam and hydro comparisons.

Since steam station heat rates are fast approaching an irreducible minimum, it is to be expected that in the future the savings in operating cost resulting with the new steam capacity additions will be less of a factor in reducing the cost of providing additional generating capacity by steam. However, the making of superposed capacity additions has introduced a new factor into this situation. If the high-pressure boilers provided in connection with superimposed capacity additions were of the same efficiency as the low-pressure boilers they replace, the heat rate of the new capacity provided by superposing would be approximately 5 000 Btu per kw-hr. However, the new high-pressure boilers provided are usually so much higher in efficiency that the new superposed generating capacity can be loaded with an actual reduction in fue requirements. In other words, the new generating capacity has a negative coal rate. Thus, the savings in operating cost made possible by superimposing, while not sufficient to cover the entire fixed costs involved, are sufficient to result in a low net cost of providing additional steam capacity.

Because the advent of superposing has resulted in reducing the net cost of providing additional generating capacity, it has tended to make inter-connections, peak-water power, and pumped-storage installations less economical than they were previously. However, this effect is only temporary and will be followed by a reverse effect. Superposing can only be utilized as long as low-pressure capacity remains which is economically adaptable to superposition. The low-pressure plants superposed upon will be rendered almost as efficient as new condensing capacity that could be added at present. Thus, when the time comes that further superposing is no longer economical, there will be less inefficient generating capacity in operation to be replaced by the new generating capacity. Hence, the operating cost saving will be greatly reduced. As a result, conditions may become more favorable for the development of peak hydro than they have been for some time. Considering that the need for peak hydro also increases with the load peak (because of the resulting greater amount of low load-factor peak that can be economically carried by hydro), it does not seem unreasonable to expect a resumption in development of hydro capacity after the possibilities in superposing have been exhausted.

It is thought that in many cases the difficulties in properly evaluating the reliable capacity values of run-of-river hydro-electric plants have resulted in their not being given full credit. Because during a large part of the year little output can be definitely depended upon from the run-of-river plant, its peak-carrying capacity value has been regarded as little more than that resulting with the minimum stream flow. In reasoning thus, it is forgotten that steam capacity cannot be relied upon as being available at all times. It is only by providing spare units that the probability of having sufficient capacity available to carry the load can be made great enough to meet the practical requirements. Since the availability of steam capacity and even the amount of the system peak to be carried are subject to chance variations, it is proper to evaluate water power by considering its effect upon the total probability of having power available to meet system needs.

In making such evaluation, allowances should be made for the ability to schedule steam-unit outage times so as to offset the seasonal variation in hydro-electric output, and also for the ability of the run-of-river hydro to give full output for short periods at times of emergency, by drawing upon its limited storage. Where the potentialities of remaining undeveloped water powers are properly determined, it is believed that many of them will be found economical even though they are much less favorable than Niagara.

In Fig. 26, Mr. Justin shows the firm capacity of a hydro-electric plant to increase in direct proportion to the system load. Because such a rate of increase of firm capacity would require increasing amounts of controlled energy output, it will be evident that the firm capacity of a given hydro-electric development increases at a slower rate than the system load. Usually, the firm capacity of a given hydro-electric development varies approximately as the square root of the system load, assuming, of course, that the shape of the load-duration curve remains about the same.

Mr. Sporn has made a valuable contribution in showing that it is not economical to transmit steam power over long distances. It should be stressed, however, that Mr. Sporn's comparisons are made for conditions not frequently met in actual practice. As a result, the comparisons show a much lower cost over the entire range of load factor, with transmission by freight over a distance of thirty miles, whereas it is common practice to transmit power electrically over this distance rather than resort to local generation. The failure of the comparison to correspond with what is found economical in actual practice results because it does not take account of the differing amounts of spare generating capacity required or of the necessity for inter-connection lines even when there is no normal delivery of power. Further, there is a practical necessity, in almost any case, of transmitting power for at least some distance from the generating station to the centers of distribution. Hence, if the generating station is displaced from the center of the territory supplied (in order to locate it at a coal mine, for example) the additional transmission cost involved is usually much less than the total cost of transmission over a similar distance, shown in Fig. 26.

Thus, because the actual conditions encountered are different from those assumed in Mr. Sporn's comparisons, it is frequently economical to transmit power over long distances rather than to resort to local generation involving freight delivery. Although Mr. Sporn's cost determinations necessarily had to be limited to some simple set of conditions, the variations from the conditions of actual practice should be kept in mind so as not to arrive at any wrong conclusions as to the economy of power transmission. Because Mr. Sporn's results would seem to indicate that transmission by freight is cheaper over all distances for loads of less than 90% load factor, it must not be inferred that the many lines now in operation for transmitting steam power do not represent sound investments.

V. M. Marquis,[36] Esq. (by letter).—The paper by Mr. Orrok covers the progress made in the generation of energy by heat engines in such a thorough and interesting manner that it does not leave very much to be discussed. However, there are a few points on which additional comments may be of value.

It is only necessary to compare the Newcomen engine of 1770, which required an output of 416 000 Btu per kw-hr, with the present high-pressure steam turbine unit and mercury vapor units, which require an output of only 10 000 or 11 000 Btu per kw-hr, to see the great strides that have been made in the art of generation. However, the end has still not been reached. Development of materials suitable for use at higher temperatures and pressures, the use of higher speeds, and the possible further adoption of the binary cycle, should all result in a gradual increase in the efficiency of the heat engine.

The excellent results already obtainable with the steam turbine are shown in Table 2 of Mr. Orrok's paper. Mr. Orrok is dealing with the progress that has been made in the generation of energy by heat engines, and Table 2 most certainly emphasizes the results possible in a modern high-pressure plant. However, in any discussion with reference to a practical system, it must be remembered that all the plants are not of this vintage, and in discussing generation costs it is necessary to take into account not only the latest and most efficient plants in the system, but also the older plants. Some of the latter will have somewhat higher generation costs, but they are, nevertheless, perfectly good plants and cannot immediately be superseded by more efficient ones. They, of course, assume a different position on the load curve than the more modern plants; that is, they operate over the peak periods and normally have a very low annual load factor. On this basis they cannot be economically replaced by new capacity. In any practical system allowance must also be made for reserve capacity, and, as stated by Mr. Orrok, this has not been included in his calculations.

The generating costs are made up of operating costs and fixed charges. Operating costs may vary considerably with annual load factor. Again, if the total operating costs given in Table 2 are plotted against load factor, the result is practically a straight line. Although this would probably be nearly correct for a new modern plant with low maintenance and labor costs, and with a single boiler supplying all the necessary steam, nevertheless, in most plants—and especially in the older ones, with many turbine and boiler units—it is necessary to consider the fixed and variable portion of the operating costs. For example, there is a certain portion of the fuel charge which is a fixed cost and a certain portion which is variable. The same holds true to a certain extent with maintenance and labor. The net result is that the curve of operating costs is fairly flat at high annual load factors, but rises considerably at lower load factors. (This is definitely shown by Fig. 30 in the paper by Mr. Sporn.) Therefore, in a practical system that includes a variety of plants, from the most efficient "modern" type to those built 10 or 15 yr ago, operating costs at low annual load factors might be expected to be considerably higher than those given in Table 2.

---

[36] With Am. Gas & Elec. Co., New York, N. Y.

R. L. SACKETT,[37] M. AM. SOC. C. E. (by letter).—The fine review by Mr. Orrok emphasizes the contribution which the mechanical engineer has made in increasing the efficiency and size of generating units, while maintaining the capital cost per kilowatt practically constant. It is characteristic of modern civilization to continue development in one way or another. However, as the possible rate of increase in efficiency is now much reduced, it follows that the power industry must necessarily turn soon to those other factors of power cost—distribution and consumption—and give them more serious consideration than it has in the past.

Mr. Orrok's paper also calls to mind a modern problem in engineering education. One hears a great deal about the importance of "emphasizing fundamentals." The teacher of mechanical engineering has been compelled to emphasize them. When a student, the writer was required to design a Scotch boiler. No one asks the student to-day to design a Scotch boiler. The subjects that had to be considered as examples then were few, such as a straight-line engine, a fire-tube boiler, and a gasoline engine. To-day, the field is so complex that there is no time to go into the design of the modern boiler—or even the design of modern steam turbines, which is more important—and the teacher is compelled, in illustrating given problems, to insist more and more on the fundamental principles than on involved, time-consuming designs that after all are of specific value only in one particular field.

The writer wishes to comment also on an item which Professor Freeman mentioned but did not stress, namely, the displacement of human labor in industry as a result of reductions in the cost of power.

Americans take considerable satisfaction in the historical fact that, over a long period of years, the percentage of the population actively employed in industry has increased. However, as long as present motives continue, there is every expectation that the adoption of new labor-saving devices will also continue, and, with it, the resulting displacement of labor. The maladjustments do not concern the producer of power in large units; they are rightly the problem of the producer of goods, because it is in his plants that they occur.

That some manufacturers are already assuming the social responsibility for readjustment in such cases, is evidenced by the following incident, which came to the writer's attention some months ago: A certain rubber company was proposing to install a machine to cut out rubber soles that formerly had been cut by hand. The machine required two or three operators and would displace about forty men. The managers called in the employees and stated the facts, but said: "We are going to train you for other jobs. The installation of this machine will increase our products and the production of other departments and we will have additional jobs here and there for which you will be trained." The consequence was that there was no disturbance in that case and the employees were continued with as good or a better rate of pay.

---

[37] Dean Emeritus of Eng., Pennsylvania State Coll., State College, Pa.

Certainly, the responsibility for such readjustments lies, partly at least, with engineering management. Yet engineers have done very little, from an educational standpoint, about it. Where is there an educational institution within an industry or public organization whose purpose it is to assist in these readjustments? This point is to be emphasized: These men who are displaced from jobs have little facility for re-training themselves for other kinds of work.

Consequently, there are certain social influences of considerable importance that are involved in such a readjustment, and for these reasons, it seems the responsibility is even greater on engineering management to assist in this task. Certainly, engineering can do a great deal, most of which is now being done in technical institutions, night schools, or in engineering extension courses, to reach into the industries and assist these men to better jobs—or, at least, to different ones.

D. J. McCormack,[38] Esq. (by letter).—A few supplementary statements may be added to the paper by Mr. Rogers on the hydro-generation of energy. Because of the relatively high cost of low-head hydro-electric plants (most of which are situated in the Middle West and along the Atlantic seaboard in the most densely populated section of the United States), and the widely variable flows usually encountered in such developments, it has been necessary to reduce all costs of such plants to a minimum to justify their development, or even the re-development of an existing plant. Hydro-electric engineers have been faced with the problem of cutting costs wherever possible to effect this purpose, particularly in the face of rising unit prices. In consequence, turbine builders have constantly been urged to develop higher-speed units. In this connection, the introduction of the Kaplan adjustable-blade turbine has made it economically possible to develop and re-develop many low-head water powers that otherwise could not have been considered. Records show that an adjustable-blade turbine plant has exceeded the kilowatt-hour output of a Francis-type turbine plant or a fixed-blade turbine plant, over the same year and on the same river, by 10 to 30 per cent.

Where close regulation is not required, electrical operation of the runner blades can be used. This method has the disadvantage of not being able to pick up load quickly to prevent a consequent drop in speed on sudden load demand. If the flow of the river varies quite gradually and shut-downs are permissible, hand-adjusted runner blades may be used at a slight saving in initial cost.

It has been determined at the Safe Harbor Plant, on the Susquehanna River, that the last unit installed, which has machine-finished blades, will safely carry a 5 000-hp greater load within cavitation limits than the other units, which do not have machined blades.

Impulse wheels, because of the higher efficiencies (88 to 90%) now obtainable therewith, and because of their simplicity of construction, durability, and desirability from an operating standpoint, are at present being adopted more generally than reaction turbines for heads of from 500 ft to 800 ft. It is recognized that because of the rapid wear of the runner seals and of the joints at the top and bottom of the gates under the higher heads, reaction turbines must be completely overhauled every few years in order to maintain efficiency. A well-designed impulse wheel will maintain high efficiency over a much longer period, and, if the tail-water variation is within a narrow range (as it generally is), an impulse wheel with a vertical setting can be placed very close to tail-water to increase the effective head.

I. E. MOULTROP,[39] ESQ. (by letter).—The paper by Mr. Sporn is extremely timely. His fair and comprehensive treatment of the subject of generating cost should be thoughtfully read by every one interested because it gives the complete story in terms every one can understand. For the first time the three chief items in the cost of electric energy as delivered to the customer are analyzed collectively and their relative values in terms of dollars are clearly presented.

Many people, impressed by the size of some spectacular steam or hydro-electric generating station, make the erroneous deduction that the cost of such stations is the chief money outlay for the system. Reasoning from this incorrect assumption, they naturally conclude that electrical energy obtained from water, running freely down hill, must be much less costly to produce than that derived from coal, which must be bought. This would be more nearly correct if no other items were involved and the hydro-electric station was located near the load center.

The large area of the storage reservoir seldom impresses one as being an item of considerable expense. Moreover, the layman does not realize the wide range between flood and low water and the comparative duration of each, and the fact that the hydro-electric generating station must meet both extremes. Finally, in a hydro-electric development, the greater part of the money outlay is made in the initial construction; the power-house and its appurtenances are, in general, the only parts that can be built initially to just the right size to meet the demands of the existing load. Hence, considerable of the invested capital may actually be idle for a long period. This factor may be quite important, but it is seldom appreciated. The steam generating station, on the other hand, can usually be built just to meet the existing load requirements, and comparatively little capital need be tied up awaiting future demands.

The comparative costs of steam and hydro-electric generating stations, as given in the paper, are illuminating. As the cost figures are taken from Federal reports they cannot be questioned, except that one may wonder whether complete data, such as an engineer requires, are always included. Engineers familiar with both types of stations might feel that the hydro-electric station was somewhat favored.

Coming to the other two items of power cost to which the public generally gives little thought, Mr. Sporn clearly points out their greater relative importance. It is indeed unfortunate that the costs of the transmission system and of the distribution system are so little understood. If the public knew that the greater portion of the invested capital was spent in building these parts of the system there would probably be less popular agitation for hydroelectric stations.

---

[39] Cons. Engr., Belmont, Mass.

It is significant that, on the average, a ton of coal can be transported about 140 miles at a lesser cost than that of transmitting the electrical energy produced by that ton of coal for a similar distance. If this were common knowledge, one would hear fewer arguments for developing a greater number of the remaining water-power sites—especially as these sites are usually quite undesirable and far from the load center.

Likewise, the cost of the distribution system is little realized. In the cities it is usually underground and, therefore, cannot be seen. Moreover, it is not generally appreciated that the cost of maintenance is high. Rural electrification, badly as it is needed, can be made possible only by developing a very cheap and none-to-reliable rural distribution system and by materially increasing the energy consumption per customer. Such a system could not be used in municipal areas.

Throughout the paper Mr. Sporn has been very conservative, basing many of his data on Government sources which must be accepted as correct. The curves of generating costs (Fig. 30) and of transmission costs (Figs. 31 and 32) are most illuminating and should be studied with care by all who are inclined to discuss superficially the subject of electrical energy costs.

The final paragraph, indicating future trends, is very sound and again conservative. The best engineering minds in the world in mechanical and electrical work are engaged in studies to simplify apparatus, reduce its cost, and improve its efficiency. One would be very rash to predict what the end will be, but utility engineers are looking forward to much more improvement. The 2 400-lb steam plant which Mr. Sporn now (1938) has plans for building is a decided step in advance. It is to be hoped that similar progress will be made in the transmission and distribution fields, and there is reason to expect that these hopes will be realized in due time.

M. M. SAMUELS,[40] ESQ. (by letter).—In presenting this discussion the writer assumes that the Symposium was not intended to prove or to disprove any political theories or opinions, but that it was intended as an engineering discussion, whose purpose can never be anything but fact finding.

Attention may well be called first to the surprising diversity of terminology among the authors of the various papers. If every one were to continue using his own favorite terms, engineers would soon be in the position of those who built the tower of Babel. True, many definitions have not yet been established as American Standards Association (ASA) standards; but the proposed ASA standards have been approved by all the respective sub-committees of the various societies and should be used by engineers. Thus, Mr. Orrok speaks of "use factor" and Mr. Justin of "capacity factor," both meaning what the proposed ASA standards term the "plant factor." Mr. Justin has his own definition for "utilization factor," whereas the proposed ASA standards define the utilization factor as the ratio of peak to capacity. Those who have served on standardization committees know that frequently a term which appears at first as the most obvious has to be dropped for one reason or another. Considerable confusion will be avoided if all engineers will speak the same language, even if some of the terms are not to their individual liking.

---

[40] With Federal Power Comm., Regional Office, New York, N. Y. Any opinions expressed herein are the writer's own and have neither been approved nor disapproved by the Federal Power Commission.

Considerable confusion in the discussion is brought about by a diversity of appreciation of the significance of the various factors in the cost comparison. Credit is due to Mr. Orrok for dropping the method, previously used by him, of setting up cost comparisons on a load-factor basis and substituting for it a comparison on a plant-factor basis. Mr. Justin, too, sets up cost comparisons on the plant-factor basis. Mr. Sporn, however, presents his cost data on the load-factor basis. Although other important conditions which would give the data definite meaning are no doubt known to him, to the reader such data are meaningless. The load factor is the ratio of the average load to the peak; it is not even necessary to know the scale of the load curve to establish it. A plant of unknown size may have a peak of 90 000 kw and an average load of 45 000 kw, resulting in a load factor of 50 per cent. The same plant may have a peak of 9 000 kw and an average load of 4 500 kw, resulting also in a load factor of 50%; but the fixed charges per kilowatt-hour in the second case will be ten times as high as those in the first case. Thus, for the same power-house, and the same load factor, the fixed charges per kilowatt-hour can be made to be almost anything any one desires. Why not follow the example of Mr. Orrok and Mr. Justin and set up the comparisons on a plant-factor basis? but if load factor it must be, the data presented by Mr. Sporn would become of great value if he were to state the capacities and peaks to which the various load factors relate.

There are many other uncertainties in cost set-ups on the basis of load factor. For instance, the difference between a load factor computed from the instantaneous peak and one computed from the 60-min peak may be as much as 20 per cent. Possibly, Mr. Sporn's curves and figures are based on the assumption that peak is equivalent to capacity, in which case the load factor would be equivalent to the plant factor, and the curves and figures would assume a definite meaning, even if in reality there is scarcely a plant which, in any one year, to say nothing of the average over the life of the plant, will have a peak which is exactly equal to the capacity.

Even when comparisons are related to plant factor great caution is called for. Only in the case of an isolated plant can a comparison be made between hydro-electric and steam on the basis of the same plant factor for both. With power systems as they exist to-day, such an isolated plant situation will scarcely ever present itself. Generally, there will be a system which can absorb all the energy that a hydro-electric plant can generate, as indicated by Mr. Justin. For such cases higher plant factors must be assumed for hydro-electric than for steam. Table 6 shows that on the whole, in the United States, the plant factors of hydro-electric plants have been considerably higher than those of steam plants, which means that on the average considerably more kilowatt-hours per annum per kilowatt of installed capacity are generated by hydro-electric plants than by steam plants. This definitely indicates how little value there is in discussing such a subject in a general way. Rational plant-factor assumptions can only be made in given cases, and even then it is of great importance not to overlook the fact that the plant factor on which any cost comparison is made must be an average throughout the entire life of the plant.

TABLE 6.—APPROXIMATE OVER-ALL PLANT FACTORS* OF THE ELECTRIC LIGHT AND POWER INDUSTRY IN THE UNITED STATES

Description	1926	1927	1928	1929	1930	1931	1932	1933	1934	1935	1936	1937
All hydro plants..........	45	46	49	48	41	35	39	40	39	45	45	48
All steam plants..........	30	29	29	31	29	28	21	22	25	26	32	34

* Percentages computed from basic data in *Electrical World*, January 15; 1938.

It is to be noted that the various authors in this Symposium use different percentages for fixed charges, making it difficult to compare their resulting costs. In reports published elsewhere the differences are even greater than they are in this Symposium. In many cases these variations are brought about by the fact that the several authors include different items under the term, without stating definitely what these items are. To the banker, the term "fixed charges" generally means only interest and amortization of long-term debt discount and expense. For railroads, the Interstate Commerce Commission includes also rentals. In modern utility accounting, the term is not used at all. As related to electric utilities, it is only used as a convenience in estimates, and in this case the diversity is considerable. Some include even income tax and others exclude even depreciation. Therefore, each author, when using the term, should state which items he includes, as does Mr. Orrok in his paper. The cost of money may vary considerably. The depreciation depends on the assumed life of the plant, which, in the case of new steam plants to be built, is to a great extent a matter of design policy. The assumptions vary from 15 yr to 30 yr. On the basis of straight-line depreciation this would represent a variation of one of the items in the fixed charges from $6\frac{2}{3}\%$ to $3\frac{1}{3}\%$ per annum. In 1920, the U. S. Geological Survey reports a total of 2 598 steam plants in the United States, and in 1935, only 1 491. Since the 1935 figure includes a considerable number of new plants, and since units have been removed from the remaining plants, it is evident that the great mortality of steam plants would possibly make a design policy of 15-yr life for steam plants rational. On the other hand, in 1920, the U. S. Geological Survey reports a total of 1 172 hydro-electric plants in the United States, and in 1935 as many as 1 523, an indication of a very low mortality. Thus, it is evident that, unless a definite case is at hand and all the details are presented so that they can be analyzed and criticized, the discussion will not mean a great deal.

Another feature which is scarcely ever mentioned is the comparative reliability of service. It costs more to render good service than it does to render poor service, and the cost per kilowatt-hour on a system having two outages per year cannot be fairly compared with that of one having twenty outages per year. Is a steam plant at load center more dependable than a remote water-power station with a transmission line; and what kind of a transmission line—single circuit, double circuit on the same structures, double circuit on separate structures, etc? All these features enter into cost, and unless they are known and included in the cost comparison, such comparison means very little.

As to the individual papers: Mr. Orrok's fine presentation of the progress made in fuel economy would have been much more nearly complete if figures had been presented to show the additional fixed charges involved in the higher fuel efficiency. Mr. A. E. Knowlton recently presented a tabulation[41] of large plants from which it would appear that, above a certain point, the saving in fuel brought about by higher steam pressure is offset by higher fixed charges. At the present stage of development such a point should not be overlooked.

Mr. Rogers, in his discussion of the frequency problem, fails to mention that according to Dr. W. M. White[42] this difficulty may be solved in the future by direct-current transmission.

Even if the Symposium is entitled "Economic Aspects," it would seem necessary at this time to sound a warning that, in the search for economy, reliability of service should not be overlooked. Recent widespread outages throughout the country seem to indicate that "Btu-chasing" has reduced the reliability of service of many an important inter-connected system to a level not much higher than that of an isolated little Diesel plant. Mr. Justin's paper seems to reflect the philosophy of "Btu-chasing" regardless of reliability of service.

The first sentence in Mr. Sporn's paper, calling attention to the fact that the cost of generation is only a small part of the cost of a kilowatt-hour delivered to a customer, is to the writer's mind the most important statement of his paper and possibly of the entire Symposium. Actually, the problem of deciding in an individual case whether a steam plant or a hydro-electric plant should be built, has now become a comparatively simple (although at times lengthy) problem of power engineering. It is indeed surprising that there is still so much general discussion on the subject. It is no secret that among engineers a general discussion of the question of "steam *versus* hydro," when no definite case is at hand, is considered a waste of time. This is not so with distribution. Only a few years ago engineers frowned upon distribution as being "low-brow" engineering, or no engineering at all; it was considered a job for the line foreman and storekeeper. More recently, however, engineers have been devoting considerable time to the study of distribution problems, and distribution has become respectable, even "high-brow," engineering. The results are astonishing. Definite problems have been crystallized and partly solved. Mathematical analysis has been applied to distribution studies, and the history of electrical engineering shows that when mathematical analysis is superimposed on operating experience, fine results are inevitable. It may be safely predicted that before long distribution engineering will be the most important part of electrical engineering. Professors may even consider the advisability of devoting a little less attention to machine design and more to the physical and mathematical fundamentals of distribution. The previously mentioned fault in Mr. Sporn's paper, of basing cost on load factor, is particularly evident in Figs. 33 and 34, which present a comparison of cost between shipping energy in the form of coal on the one hand and electricity on the other. It is unfortunate that these important comparisons are meaningless. No doubt, Mr. Sporn will be able to supplement curves on a plant-factor basis and thus give this important set of data a definite meaning.

---

[41] *Electrical World*, October 9, 1937.

[42] "Technological Trends and National Policy," National Resources Committee, 1937, p. 281.

Mr. Sporn's expression of doubt about the economy of transmission over very long distances deserves serious attention, particularly because he is no doubt one of the outstanding and most outspoken authorities on transmission problems. Here, too, it would have been helpful if comments had been included about comparative reliability of service.

It would be interesting to know what method of weighting was applied in establishing the average transmission distance on the specific system as 60 miles, and also what the longest distance is, and what, if any, sad experiences were had with this longest distance?

Mr. Freeman's paper presents definite statements and questions without presenting a single figure to substantiate the statements or the reasons for the questions. It is impossible, therefore, to discuss this paper. One of his statements, however, is of such great importance that it deserves further elaboration: "The old economic problem was how to produce enough; the new problem is how to dispose of all that can be produced." As related to electric energy, the problem is how to fill out the load curve and thus reduce fixed charges per kilowatt-hour—in other words, how to increase the load factor for a given capacity, which, again, is another way of asking how to increase the plant factor. This problem has recently become of even greater importance A few years ago it was generally hoped that the valleys in the load curves would soon fill out and that the difference between peak and average would become less drastic. Recent indications are that on many systems the opposite has happened—the percentage increase in peak has been greater than the percentage increase in consumption. Possibly this is due to shorter labor hours in industry and the speeding up of industrial production during these short hours. Even air-conditioning, which was expected to contribute considerably to load-curve improvement, is in many cases peak load. Air-conditioning has been used thus far mostly in industrial and large commercial establishments.

This problem cannot be solved by engineering alone; it must be solved by more modern business methods and more competent salesmanship. Promotional rates at incremental costs for off-peak loads have shown good results wherever they have been tried out, and where modern sales methods were used. However, the "energy salesman" has not yet entered the home. It is a safe guess that none of the readers of this discussion was ever approached by a salesman who tried to sell him the idea of using a few more kilowatt-hours per month. It is also a safe guess that a good salesman could have sold him those few additional kilowatt-hours per month. Of course, in order to sell, a salesman must at least know his own sales prices. With the present complex rate schedules this is difficult. What is needed, therefore, is, first, a simplification of rate schedules so that the customer can check his bill; and second, a drive by experienced salesmen (possibly men who have had experience in the selling of commodities against competition) to encourage the use of off-peak energy. This, no doubt, is by far the most important social aspect of power at the present moment, and, at the same time, the most important economic aspect.

E. W. **Kramer**,[43] M. Am. Soc. C. E. (by letter).—There seems to be a rather common tendency among engineers in discussing the comparative merits of hydro-electric and steam power plants, to make statements that are entirely too general—even when it is assumed, as in the paper by Mr. Sporn, that the remarks apply only to the United States. The following statements are quoted from Mr. Sporn's paper:

> "It covers the economics of steam power *versus* water power and shows that, in most cases, present-day steam power can be produced more cheaply than present-day water power. * * *"

* * * *

> "It must be borne in mind that the costs are presented from a general viewpoint. * * *"

* * * *

> "* * * that hydro-electric plants, in general, as a source of primary power, are out of the economic range. The true economic function of hydro-electric power is, without doubt, to supplement steam power. * * *"

* * * *

> "It appears definite that future power requirements will be met most economically by steam plants, located at a reasonable distance from load centers. * * *"

It is believed that these quotations, although taken from their setting, represent in part what Mr. Sporn purports to prove in regard to the future of hydro-electric construction. It is the opinion of the writer that these statements are entirely too broad. They would be almost 100% wrong for the Northwestern States, such as Washington, Oregon, and Idaho, where the steam power generated is only about 25% of the total and is economical only for the reason that it makes use of the waste products from saw-mills or has value as stand-by service. The statements would be very questionable when applied to California, for the reason that there are many undeveloped water-power sites of large capacity in California that could compete successfully with steam-electric plants using natural gas or a gas-oil combination as fuel. Finally, the writer would question the general applicability of the statements in the Rocky Mountain States, in the Northeastern States, or in the Southeastern States.

In Table 3, Mr. Sporn shows very high kilowatt-hour costs for a number of hydro-electric projects under Federal Power Commission licenses. Examination indicates that he may have been led to his conclusions by applying an extremely high annual rate to the claimed costs given in order to determine the annual fixed charges. The rate used by Mr. Sporn is 10.75%, but nothing is given in the paper to show how this rate was established. Because the major part of the annual cost of producing hydro-electric power is the fixed charge, the selection of a proper rate is extremely important. If the rate selected is too high, it will, of course, tend very strongly to lead to the conclusion that hydro-electric power is more costly than steam, since the investment in steam is relatively less and the operating cost more. It is the writer's opinion that a well-established, conservatively financed and managed utility with a large and growing market should be able to hold its fixed charges on hydro-electric projects (not including fixed charges on transmission and distribution) to 8% or less. The following build-up of an annual rate, which the writer believes would be applicable to California, is presented for a hydro-electric project with an installation of 50 000 kw, or more, and for a head exceeding 300 ft, where a good part of the investment was in dams, tunnels, and penstocks:

---

[43] Regional Director, Federal Power Comm., Region 5, San Francisco, Calif. Any opinions expressed are the writer's own and are not to be taken as official expressions of the Federal Power Commission.

	Percentage
Cost of money	5.5
Depreciation	0.55
Insurance and casualty reserves	0.12
Local taxes	0.7
Total	6.87

It is assumed in this case that no transmission is included, since it is understood that Mr. Sporn does not include transmission in his costs in Table 3. He deals with transmission costs later.

The depreciation figure is determined on a sinking-fund basis, interest at 5.5%, and 45-yr life. The life of the tunnels and dams, of course, will greatly exceed this, although it is probable that the life of the machinery may be less.

Justine and Mervine[44] give 6.7% and 11.5% as the usual minimum and maximum total annual rates for fixed charges, and their "illustrative cases" are based on a "typical" rate of 9 per cent. It will be noted that the writer's estimate is slightly in excess of the minimum rate given, somewhat less than the typical rate, and considerably less than the maximum. The rate used by Mr. Sporn is almost the maximum rate, and it certainly is not generally applicable to the plants given in Table 3.

The principal item, the interest rate, should not vary greatly throughout the United States for a large utility which has been conservatively financed and managed. Possibly 6% might be used. A slightly higher rate for depreciation than the 0.55% used by the writer could be used for low-head plants, where the cost of machinery and equipment represented a larger fraction of the total cost. However, assuming a much shorter life and taking obsolescence into consideration also, this item should not exceed 1% on a sinking-fund basis. This would mean an average life of slightly more than 30 yr with money at 6 per cent.

The operating and maintenance charge should not exceed $0.80 per kw-yr. This is equivalent to the rate of 0.4% on the investment for a plant costing $200 per installed kilowatt, and would bring the total annual rate (fixed charges plus operating and maintenance cost, but not including general and administrative expenses) to 7.27 per cent. The writer is somewhat familiar with the Western plants listed in Table 3 and can see no reason why a much higher rate should be applied to the capital cost of these plants if conservatively financed. It is evident that the application of this annual rate to the other hydro-electric projects shown in Table 3 will lead to very different conclusions from those of Mr. Sporn.

---

[44] "Power Supply Economics," p. 153.

The foregoing discussion indicates strongly the importance of financing hydro-electric projects at the lowest possible rate, since a difference of only 1% in the interest rate will represent a difference of approximately 12% in the total annual cost and might easily be the deciding factor in determining the economic feasibility of the project.

Under the heading, "Trends in Hydro-Electric Installations," Mr. Sporn comments that the most economical sites were developed long ago, and that those which have been exploited recently have, in general, been less attractive. The inference from this statement, namely, that the sites still to be developed are even less desirable, is possibly applicable in many localities to projects requiring a medium amount of capital investment. The statement, while possibly still true to some extent, is misleading if applied too generally or to large projects (requiring investments of, say, $40 000 000, or more, to use a rough figure) such as the Boulder, Bonneville, or Grand Coulee projects in the West, or the undeveloped projects on the St. Lawrence River in the East, and on some of the larger streams in other parts of the United States. In many cases, such projects have not heretofore been undertaken on account of their size.

The writer does not wish to bring into this discussion the advantages or disadvantages of the construction of large hydro-electric projects by the Federal Government. However, the fact that the Government used a 4% interest rate in determining the charge for power from the Boulder project, and can undoubtedly borrow money at a lesser rate, should not be overlooked in considering the feasibility and probability of the construction of extremely large projects requiring an investment that, because of its magnitude and because of the many uncertainties involved, such as the growth of load to absorb the large output, could not be financed by a utility—or for that matter by a municipality, or even a State. Sound Federal financing can spread the necessary returns to recover the investment, including interest, over a long period to compensate for small initial returns. Using 4% as the cost of money, and adjusting the interest and depreciation allowances accordingly, the annual rate for fixed charges given earlier in this discussion reduces to 5.65%, which is only little more than one-half the rate used by Mr. Sporn.

It is the writer's opinion that each hydro-electric and each steam-electric project necessarily has to be considered carefully on its merits—that no general assumptions can be made as to their relative advantages or disadvantages. As a general rule, they are at their best when inter-connected. The question as to which one will supplement the other will depend on the relative magnitudes of each type connected to the system, and this relation, in turn, will vary according to the locality.

PAUL E. GISIGER,[45] M. AM. SOC. C. E. (by letter).—The paper by Mr. Sporn offers a welcome clarification of the essential points pertaining to the cost of electrical energy. Although the facts and figures undoubtedly give an excellent and clear picture of the distinct elements of which the cost of power is made up, it may be questioned whether some of the conclusions drawn are not a shade too pessimistic as far as the future of hydro-electric power generation is concerned.

In the technical literature of the last fifteen or twenty years predictions of the decline of the proportion of hydro-electric power in the total power supply of the United States can often be found, but such predictions have not been confirmed by later statistics. In 1920, hydro-electric plants produced 37.1% of the total energy generated by public utility central stations. In 1924, this percentage was 33.8, and, in 1933, it was 40.7; in the 12-month period ended October 31, 1937, it was 35. These figures show variations governed largely by the annual variations in river flow, but as a general trend, it appears that water power has kept its own during a period when the efficiency of steam-generating apparatus has greatly increased and the annual output of central stations nearly doubled. One factor in this is probably the spreading recognition of the fact that the combination of hydro and steam power is very often more advantageous than the use of either one alone. In this regard, it may be noted that, in 1920, among the large cities on the Atlantic seaboard, Baltimore, Md., was the only one which received large blocks of hydro-electric power; at present (1938), Washington, D. C., Philadelphia, Pa., Providence, R. I., and Boston, Mass., are also supplied to a considerable extent with energy generated in hydro-electric plants. To cite also a foreign example of the same trend, the Metropolitan Area of Paris, France, which lies much nearer to coal fields than to water-power sites, was, until 1927, supplied to less than 1% with hydro-electric power while in 1936 the proportion of hydro-electric energy was 36 per cent.

The writer cannot agree fully with Mr. Sporn's statements that hydro-electric plants, in general, as a source of primary power, are out of the economic range, and that as a general rule no hydro-electric plant is self-sufficient. These opinions hold only within geographical and other limitations. They are undoubtedly correct for large sections of the United States, but their application to other parts of the world—for instance, to Canada—would be out of place. If a hydro-electric plant can be built at some figure near the average of the costs quoted in Mr. Sporn's paper, within a reasonable distance from the places where its output is to be used, its economic justification depends ultimately on the greater or lesser variations of stream flow. In the northeastern section of the United States these variations are, in most cases, of such magnitude that only by the most careful analysis, taking full account of all limitations and possibilities which depend upon stream flow and its improvement by storage as well as of the manner in which the energy can be fitted into the daily and annual load curve of a distribution system (or to what extent it can replace steam energy), is it possible to determine whether development of a given water-power site is economically justified, that is, preferable to steam power?

---

[45] Structural Engr., Pennsylvania Water & Power Co., and Safe Harbor Water Power Corp., Baltimore, Md.

On the other hand, if a hydro-electric plant can be built at, say, $140 per kw, and the stream flow allows it to be operated at a daily and annual load factor of not less than, say, 50%, it is not difficult to show that steam power at its present, or even a higher, efficiency will cost more to generate, and a substantial margin remains to cover the cost of transmission. It is true that in the Northeastern United States there are few water-power sites that satisfy such requirements, but next door, in Canada, they are the rule rather than the exception. Consequently, steam plants produce less than 5% of all the power generated in Canadian public utility plants.

With the foregoing, it is intended to show that, for the present at least, the relative economy of steam as against hydro-electric energy depends to such an extent on place and circumstance that no general statement can be made declaring one to be cheaper, unless the specific conditions are given to which it applies.

One point which appears to be overlooked sometimes when costs of steam and hydro-electric power are discussed, is the influence of the prevailing rates of interest on the relation of these costs. It is evident that, since capital cost is normally more than 90% of the cost of hydro-electric power, whereas the cost of steam power is made up to only about 50% of capital charges, a change in interest rates will affect the cost of hydro-electric power more than the cost of steam power (see Fig. 37, in this connection). The figures on which Fig. 37 is based correspond to cost figures used in Mr. Sporn's paper. It is assumed that the kilowatt of installed hydro-electric capacity costs $160 and the kilowatt of installed steam capacity, $100. The annual cost of operation of the hydro-electric plant is taken at 75 ct per kw of capacity and all other charges exclusive of interest at 5% of cost of installation. In the case of the steam plant, the cost of operation is taken from Fig. 30 of Mr. Sporn's paper for an annual load factor of either 45.6% or 57.0%, corresponding to either 4 000 or 5 000 hr of operation per yr. All other charges exclusive of interest are assumed to be 7% of the cost of installation, making the capital charges for the steam plant 2% higher than for the hydro-electric plant, as assumed by Mr. Sporn. No transmission charges were added in case of steam energy,

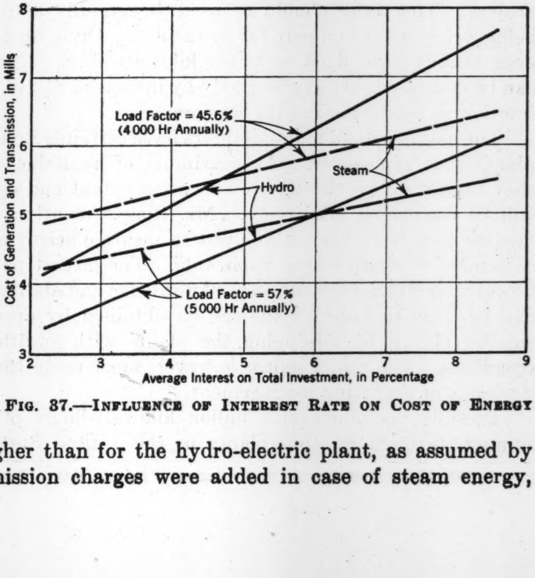

FIG. 37.—INFLUENCE OF INTEREST RATE ON COST OF ENERGY

while in the case of hydro-electric energy, such charges have been added for a transmission distance of 50 miles. Transmission costs for this distance and for the load factors used were taken from Fig. 32 of Mr. Sporn's paper. They were added without change to the kilowatt-hour cost resulting from a 5% interest rate, while for other interest rates they were increased or decreased in proportion to the total cost exclusive of transmission.

The resulting curves of total cost per kilowatt-hour show plainly that a reduction in interest rates is relatively more favorable to hydro-electric power than to steam power and *vice versa.*

F. A. DALE,[46] M. AM. SOC. C. E. (by letter).—The cost of generating electrical energy by means of falling water involves four major factors: (1) The cost of the development; (2) the quantity of water available; (3) the efficiency at which the plant is capable of converting the water into energy; and (4) the efficiency at which the plant *does* convert the water into energy. Mr. Sporn has emphasized the fact that the preponderant portion of total hydro-electric energy costs is the fixed charges on investment. Mr. Rogers has presented a masterly summation of what the designers have accomplished in furnishing equipment which is capable of converting a very high percentage of the water energy into electrical energy.

Additional emphasis should be placed on Factor (4) in the cost of generation, namely: That the final cost per kilowatt-hour depends to no small extent on the proportion of possible kilowatt-hours actually generated. From the point of view of cost of development, or fixed charges on investment, the investment cost for delivering water to the power plant may be 75% of the total cost of the project. The water, therefore, is certainly not free. Unlike steam plants, for which fuel can be purchased as it is used, the administration of a hydro-electric plant must purchase, in advance, the entire fuel supply for the life of the project. The water should be used as carefully and effectively as if it were being weighed out and paid for by the ton. Dividing fixed charges by kilowatt-hour output gives fixed costs per kilowatt-hour. The cost per kilowatt-hour can be decreased just as effectively by increasing the denominator of this simple fraction as by decreasing the numerator.

The designers and manufacturers have certainly done their part in furnishing plants that can convert the maximum of available energy. Unfortunately, they cannot follow through to any great extent and insure that their products will be used most effectively. Mr. Rogers mentions automatic load control devices that have been developed to insure efficient operation and which are extremely effective where applicable. The largest part of energy generation, however, is still dependent on the knowledge and ability of the operator. Much can be done to improve the results obtained by operators, especially in the smaller plants, by equipping the plants with additional devices to aid the operators. The major gains, however, must come through the initiative and demands of operating management.

Possibly, as much as a billion kilowatt-hours of energy each year slip, unused, through existing plants in the United States. The corresponding annual increase in returns would be about $5 000 000. Saving this energy is a problem which engineers will solve if given the opportunity.

---

[46] Chf. Engr. and Mgr., Santee-Cooper Project, Harza Eng. Co., Charleston, S. C.

RAY S. QUICK,[47] ESQ. (by letter).—The interesting paper, presented by Mr. Rogers, covers the development of hydro-electric energy, including illustrations of actual machines which have made it possible to convert hydraulic power efficiently into mechanical energy for driving electrical generators.

One of the most interesting problems developed in the generation of hydroelectric energy on the Pacific slope has been an effective means of controlling water-hammer in comparatively long and high-pressure penstocks. Surge tanks are used where possible, but they do not provide an effective control near the power-house where pressures are high. The penstocks are of heavy construction and constitute a major part of the first cost of the development; therefore, their economical design is a problem of first importance. Where water economy is not required, the simplest means of controlling pressure rise is the synchronous by-pass. With this arrangement, the flow through the unit is constant and independent of load. The hand-operated needle of the impulse turbine with governor-operated deflector is a characteristic example. Most plants, however, depend upon seasonal storage, thus requiring a high degree of water economy, and it is here that the pressure regulator, or relief valve, finds its most valuable application.

In Fig. 4, Mr. Rogers has illustrated two typical forms of automatically controlled nozzles for impulse turbines, arranged for full water economy. The left-hand view shows the governor-operated power needle with auxiliary relief by-pass, whereas the right-hand view shows the governor-operated deflector with a slow-moving, power-needle follow up. With the first mentioned arrangement, the oil-pressure governor controls the opening of the power needle to suit the load. An oil-filled dash-pot is interposed in the linkage connection between the power and the relief needles in such a manner that a rapid closing movement of the power needle causes a corresponding or synchronous opening of the relief needle. The heavy closing springs on the dash-pot urge the relief needle to return to the closed position at a rate determined by the dash-pot adjustments and resulting in very little pressure rise. An opening movement of the power needle resulting from an increase in load first synchronously closes the relief needle if it is still open, otherwise simply bypassing the oil in the dash-pot and leaving the relief needle shut. As it is necessary to accommodate oncoming load with the relief needle shut, it is customary to adjust the rate of opening of the power needle to such a value that there is little pressure drop in the penstock and, consequently, no objectionable subsequent pressure rise. A sudden opening of an orifice on a high-head penstock otherwise would produce, first, a sudden pressure drop, followed by an excess pressure. These sudden surges are objectionable and must be prevented.

In the case of the needle-deflector combination, the deflector moves quickly on load rejection and bends the jet away from the water-wheel buckets. The power needle follows up at a rate permitted by the retardation of the water column in the penstock. Its rate of closure, therefore, is of the same order as that of reclosure of the relief nozzle of the aforementioned alternate system. Likewise, the rate of opening of the power needle with the deflector combination is at the same rate as the corresponding opening of the power needle of the relief nozzle system. It is thus evident that either method of controlling an impulse turbine results in complete water economy with gradual load changes and with wastage of water only for a short period, such as 1 min to 2 min following a sudden loss in load.

---

[47] Chf. Engr., The Pelton Water Wheel Co., San Francisco, Calif.

When they are wide open, the relief nozzles, illustrated in the foreground of Fig. 2 of Mr. Rogers' paper, discharge a jet about 8.5 in. in diameter and have

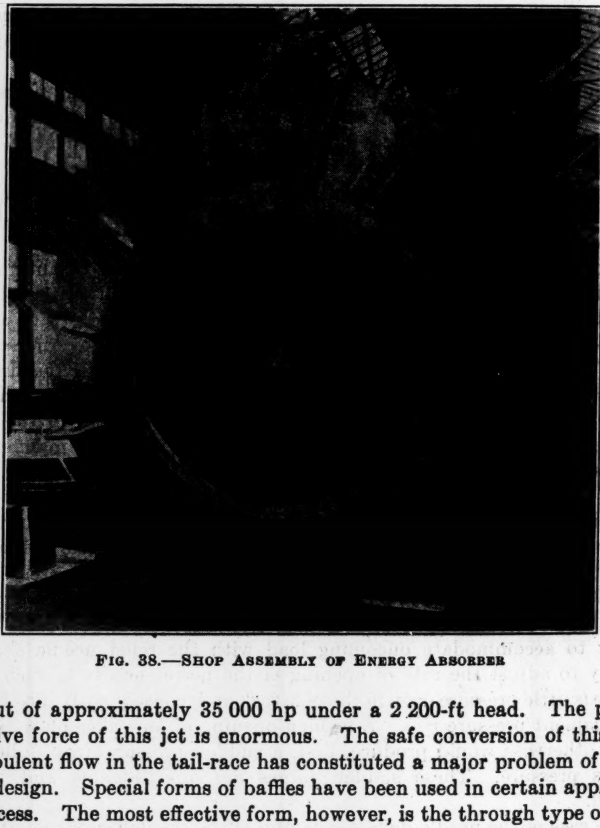

FIG. 38.—SHOP ASSEMBLY OF ENERGY ABSORBER

an output of approximately 35 000 hp under a 2 200-ft head. The potential destructive force of this jet is enormous. The safe conversion of this energy into turbulent flow in the tail-race has constituted a major problem of impulse turbine design. Special forms of baffles have been used in certain applications with success. The most effective form, however, is the through type of energy absorber, consisting of a circular open-bottomed bowl having a cone supported within it by radial ribs. The jet of water is concentric with the point of the cone, which acts to spread the water radially against the inside of the bowl, which, again, turns it upon itself and allows the discharge to mingle with the tail-race water without objectionable external disturbance. The energy absorber at Big Creek No. 2-A is a comparatively small structure.

In the case of the Francis turbine an outstanding installation of a pressure regulator and through type energy absorber will be found in Units N5 and N6 at Boulder Dam. Fig. 5 of Mr. Rogers' paper shows the shop assembly of these two turbines, the outlet for one pressure regulator connection being shown in the foreground. In this case, the pressure regulator is of the needle type using a pilot system inter-connected with the gate-shifting ring through a dash-pot control, and having a hydraulically operated main needle or plunger with mechanical interlock. The mechanism is designed so that should the movement of the main plunger be obstructed the governor will be able to close the turbine gates only at the rate permitted by the dash-pot timing, thus preventing objectionable pressure rise in the penstock even under such an abnormal set of conditions.

Under average conditions, each pressure regulator will have a capacity of 1 860 cu ft per sec under a 480-ft head which corresponds to more than 81 000 hp in the jet when computed at 80% efficiency. The energy of this water must be absorbed in order to prevent an objectionable disturbance in the tail-race. Fig. 38 shows the shop assembly of the energy absorber for the Boulder pressure regulator. The jet of water (which is approximately 52 in. in diameter) strikes directly upon the cone supported in the bowl, turning the water radially outward. The water is then turned back upon itself beneath the bowl from which it discharges downward as turbulent flow through a discharge elbow and concrete-lined horizontal outlet into the tail-race. The entire absorber is of heavy cast-steel construction, with ample provision for the admission of air into those regions near the jet where air may be required.

The pressure regulator and energy absorber system constitute a valuable contribution to the economical generation of hydro-electric energy, making possible a reliable means of controlling the speed and pressure rise with a penstock of minimum first cost. The pressure regulator also assists, in a most valuable way, in damping out periodic swinging surges that may be established under certain conditions of governing with a closed penstock system.

F. Knapp,[48] Esq. (by letter).—The paper by Mr. Rogers is decidedly not cosmopolitan. Only hydro-electric installations in the United States are discussed, and the only reference made to plants abroad is to the Shannon development in Ireland. The progress made in Europe (especially in the past few years) is of such magnitude as to be of special interest to American hydraulic engineers, but is entirely set aside by the author.

As far as impulse turbines are concerned, the largest unit—with 78 600 hp for a static head of 2 360 ft—is running in a Brazilian plant.[49] The 49 500-hp Pelton turbines for the Dixence plant in Switzerland, set the record of head—5 770 ft.

---

[48] With São Paulo Tramway, Light & Power Co., Ltd., São Paulo, Brazil.

[49] "Water-Power in Brazil, with Special Reference to the São Paulo Development," by A. W. K. Billings, M. Am. Soc. C. E., *Minutes of Proceedings*, Inst. C. E., London, 1936.

There is a marked tendency to build large impulse turbines with vertical shafts and two nozzles. Typical examples are the Etzel and the Handeck plants, both in Switzerland. The straight-flow nozzle design, already incorporated in the turbines of the Dixence plant, is an old Swiss idea, introduced just prior to the World War by V. Gelpke.

Considerable difficulty was experienced for a time with cavitation of impulse-turbine buckets, and it developed that a design successful for a head of, say, 1 300 ft, was a failure for a head of 2 300 ft. Stroboscopic observation of the buckets in motion, and refined design methods, were the means of overcoming these troubles. Efficiencies of impulse turbines are now 90% or more.

The 32 600-hp Francis turbines of the Piottino plant, in Switzerland, with a speed of 750 rpm, work under a net head of 1 060 ft, and the "back-pressure" turbine of the Zapello power station in Italy operates under the unusually high head of 1 280 ft, with 33 ft of back pressure. Each of the two sets installed develops 8 800 hp at a speed of 1 500 rpm.

Designs have been prepared for a two-stage turbine, with a maximum capacity of 37 000 hp and a total head of 1 280 ft, running at 1 000 rpm. The first stage consists of a Francis runner, designed for a head of 1 100 ft; and the second stage is a propeller runner, for a head of 165 ft, with a back pressure of 15 ft. The last part of the head would be used in a single and separate turbine of the propeller type. It is clear that such an arrangement diminishes considerably the size of the units.

It is only right to mention that the development of the high-speed turbine of the propeller or Kaplan type would not have been possible without the simultaneous advance in the design of draft-tubes, inasmuch as in these turbines the water still has about 30% of its total energy, when it leaves the runner, and this energy must be regained in the draft-tube. The elbow draft-tube of the Safe Harbor turbines (Fig. 17), is typical of this development; the other types of energy regainers, such as the hydraucone and the spreading draft-tube, are now almost obsolete—mostly for economical reasons. It is interesting to note that the elbow draft-tube, as used to-day, was first developed in the United States.

As far as laboratory testing of complete hydraulic turbines is concerned, it is noteworthy that one Swiss manufacturer has installed an aerodynamic research laboratory, using air instead of water. Besides the easier testing and the smaller space requirements this research station offers the great advantage that it is now possible to measure directly the pressures on the rotating runner blades.

The writer was surprised at Mr. Roger's statement that it is not yet possible to determine the actual benefit obtained by machining the blades as regards either performance or avoidance of pitting. It seems that with the great relative velocities in high specific speed turbines there should be a certain gain in efficiency with correctly machined blades. At least, one practical case known to the writer indicates that a correct shape of the blades, such as that obtained by machining, is of decided advantage in avoiding local cavitation.

The description of the unit installed in the Marmet plant, as given by Mr. Rogers, is most interesting. A few European installations have turbines with runners of the Kaplan type, but with fixed guide-vanes of the diagonal type. The efficiencies obtained were between those of a Kaplan and a propeller turbine.

The efficiencies of the model pump-turbine unit shown in Fig. 21 are excellent and rather promising. A unit of this type, with a Kaplan runner and diagonal guide-vane, has been installed in the Baldeney plant, in Germany.

D. S. JACOBUS,[50] ESQ. (by letter),—Such a true picture of the developments that have occurred in the generation of energy are presented by Mr. Orrok that the writer will simply add some comment concerning changes in steam boiler practice. His oldest recollection in power generation is of the Corliss engine installed in the Machinery Hall of the Centennial International Exhibition held in Philadelphia, Pa., in 1876. There was an iron platform surrounding the engine at a somewhat higher level than the floor of the building and the writer can remember standing on this platform at the time of the Exhibition. What awed him most was the tremor of the platform, and the noise of the gears and, above all, the dignified motion of the engine and its great size.

The Centennial engine consisted of two beam engines of 700 normal hp each, although they could be worked up to a total of 2 500 hp if required. The two engines were connected to a common fly-wheel, which was 30 ft in diameter, with gear teeth on its outer face. The fly-wheel made 36 rpm. Steam was furnished by twenty Corliss upright boilers of 70 hp each, the steam pressure ranging from 25 lb to 80 lb per sq in., according to the amount of power required.

A modern 50 000-kw steam turbine would generate about fifty times as much power as the normal amount developed by the Centennial engine; it could be run with steam from one or two large steam boilers in place of twenty boilers; and the entire unit would occupy less space.

The late Professor Thurston, who is the first authority mentioned by Mr. Orrok, was an indefatigable worker and was noted for the exceptional accuracy of his statistics. He was an able teacher and, in addition to foreseeing the tremendous increase in power development, he impressed upon his students the necessity of dealing with the human side of engineering. In addition to specializing in steam engines he did much in contributing to the safety and improvement of steam boilers. He often referred to the tests on steam boiler explosions by Francis B. Stevens who was instrumental in having the railroad companies subscribe toward the expense of the tests. Professor Thurston served as a member of the Federal Commission that witnessed Mr. Stevens' tests. The boilers were tested in 1875 on the United States Army Reservation at Sandy Hook, N. J. A bomb-proof retreat was built for observers. Four old steamboat boilers and five new parts of boilers built for the tests were fired until the the pressure either reached a point at which they failed by leakage or they exploded. Explosions had often been attributed to some mysterious action; these tests, however, showed that they were due to simple and preventable causes.

In addition to contributing to safety in boiler construction, Professor Thurston did much in revealing the fundamental features bearing on efficiency, in papers and books that he wrote on the subject.

---

[50] Advisory Engr., The Babcock & Wilcox Co., New York, N. Y.

Advances in the art of boiler construction have involved improvements in the furnaces and fuel-burning equipment as well as in the boiler proper. Water-cooled furnace walls have greatly reduced the time required for shutting down boilers for inspecting, cleaning, and repairs. The use of pulverized fuel has grown to a point where it is utilized in most new equipment for large coal-fired boilers in the United States. Steam pressures and temperatures of superheated steam have increased to a point at which boilers for central station and industrial plants with natural circulation are being built for 2 000-lb working pressure and more; and, forced-circulation boilers for experimental purposes are in use, that can be run at 4 000-lb pressure, which is greater than that corresponding to the critical temperature. The steam temperatures have increased correspondingly. A comparison of central power-plant boilers in 1905 and to-day is given in Table 7.

Improvements in instruments and apparatus contributed much to the attainment of present-day economies. Engineers of the "old school" will remember the uncertain results secured by the so-called barrel calorimeter which was recommended for use in the first report of the Committee on Steam Boiler Trials of the American Society of Mechanical Engineers. Professor Alfred M. Mayer, who for many years was the head of the Department of Physics at Stevens Institute of Technology, at Hoboken, N. J., and who wrote a number of important papers on his tests of inaudible sounds, etc., observed the writer operating such a calorimeter. After standing for a time without saying anything, he turned away with the remark, "Why not use a wooden horse bucket and a tin back thermometer?" After the barrel calorimeter, the so-called coil calorimeter was used. It was not until the introduction of the throttling calorimeter that results were secured of sufficient accuracy to determine the effect of different collecting nozzles in the steam main.

TABLE 7.—COMPARISON OF CENTRAL POWER PLANT BOILERS IN 1905 AND 1938

Descriptive	1905	1938
Heating surface of boiler proper, largest unit, in square feet	6 040	53 926
Heating surface of boiler, superheater, economizer, and air heater, in square feet	7 000	144 402
Working pressure, in pounds per square inch	225	650 to 2 500
Temperature of superheated steam, in degrees Fahrenheit, maximum	550	700 to 950
Maximum evaporation, in pounds per hour per boiler unit	30 000	1 000 000
Volume of boiler setting for largest boilers, in cubic feet	7 650	42 255
Height from bottom of walls of setting to center of steam and water drum for largest boilers, in feet	19	80

In the early Eighties tests of an alternating-current and a direct-current electric generator were made at the Stevens Institute for Mr. Edward Weston. There was a conspicuous lack of accurate instruments. A home-made "tangent galvanometer" was used for an ammeter for measuring the direct current, calibrating on each test by depositing copper. The "tangent galvanometer" consisted of a single circle of copper wire placed in a vertical plane, at the center of which was an ordinary magnetic compass. A voltmeter was checked by measuring the resistance of the circuit; and, a standard silver cell was built for checking voltage measurements. Both the "tangent galvanometer" and the voltmeter were affected by local magnetic influences. Finally the "tangent galvanometer" was removed to a small shed built on the campus well away from the main buildings, after which its readings were more consistent.

The troubles encountered in measuring the alternating current were still greater than in the case of the direct current and a number of methods of checking were devised. It was the extreme difficulty of obtaining reliable measurements in these tests that led Mr. Weston to develop the accurate electrical measuring instruments for which he became famous.

Much study has been made of boiler-fed water conditions. A modern steel-tube economizer requires the elimination of oxygen and carbon dioxide from the water, and necessitates the use of apparatus unknown in the older practice. The feed-water in most large central stations is as pure as the distilled water secured from a drug-store. With the higher degree of purity, troubles have developed through corrosion and corrosion fatigue of the steel, which necessitate adding chemicals to the water. Certain elements in the feed-water may lead to a characteristic cracking of the steel plates, known as caustic embrittlement, and it is necessary to provide a certain balance between the elements in the water to avoid this action. The treating of feed-water has become an art in itself, and, in order to operate an up-to-date power plant to the best advantage, the chemist must co-operate with the engineer to a greater extent than in the past.

Improvements in boiler-room auxiliary apparatus have contributed much in co-operation with boiler improvement to attain the present-day economics. The efficiency based on an accurate determination of the heat of combustion of the fuel has replaced the evaporation per pound of fuel or per pound of combustible, in reporting tests of boilers. The old-time boiler-room, where nearly everything was manually operated, has now yielded to what is more nearly an automatically, well-conducted laboratory, with a few men watching the controls of the factors bearing on combustion, steam generation rate, pressure, and temperature. Fuel feed, air supply, and fuel air ratio, boiler-feed, water level, and all pressures are controlled automatically with connections to an operating board. Its gages and meters showing the steam flow, percentage of carbon dioxide, and steam flow-air flow are symbolic of the scientific management independent of manual action, which has eliminated wastes that are bound to occur when operators must act on mere indications to guide them in making adjustments. These same elements also insure prompt response to changing load conditions and add to the safety of operation.

A marked advance has been made in the ability to predict the efficiency obtainable with the great variety of arrangements and sizes of furnaces for different fuels, boilers, superheaters, economizers, and air heaters, and the approximate rules in general use a comparatively few years ago have now (1938) been replaced by new formulations of a much more exact nature.

The Boiler Code Committee of the American Society of Mechanical Engineers has been an important factor in advancing the art and the safety of boiler construction. There are now 23 active members of the Boiler Code Committee and 40 members of the Conference Committee which is made up of representatives of those in charge of enforcing the Code in the States and municipalities that have adopted it. More than 160 men in all are continually interested and take a regular part in the work of the Boiler Code Committee, and many others having special information render invaluable help. Since it issued its first Code in 1914, the Code Committee has been successful in securing unanimous decisions in all its final actions.

Practically all steam and water drums for high-pressure boilers are now fusion welded, the old practice of riveting being correspondingly replaced. For a number of years the Boiler Code Committee was asked to formulate rules for boilers and other pressure vessels for what was at first known as autogenous welding. Certain very restricted rules were agreed on for unfired pressure vessels and for seal welding of certain joints in steam boilers. After many hearings, rules were issued in 1931 for fusion welding drums or shells of power boilers.

Radiographic examination by the X-ray or gamma ray in making nondestructive tests of the welds was the turning point in the development of fusion welding because, through its use, the safety of the welds is less dependent on the human element. The rules for fusion welding in the Boiler Code are still far from complete and are being gradually extended. This involves much painstaking work, since the use of steels and alloy steels of higher tensile strength has introduced problems requiring solution on which the best metallurgists are not yet in entire agreement.

In dealing with economy in the generation of electrical energy, one should not overlook the important saving accomplished by electrically tying in one generating plant with another and in this way insuring a continuous service with a reduced capital investment. This was one of the factors that enabled electricity to be supplied to the consumer without increased cost during the period of high prices in spite of increase in the cost of labor and fuel; and it is an invaluable aid. However, it is evident that if carried too far there may be a major shut-down due to an accident in one or more of the generating plants or on a transmission line; so there is a point beyond which it will be dangerous to go in effecting a saving by not installing spare units in a given generating station. How nearly this point has been reached, through the natural effort to avoid further investments in the present period of uncertainty as to the near future, is something of vital public interest.

JOEL D. JUSTIN,[51] M. AM. SOC. C. E. (by letter).—In view of the fact that there has always been considerable discussion as to the relative cost of transporting energy long distances, as coal by railroad, and of transporting it as electricity over transmission lines, a concrete case may be of interest.

Several years ago it was proposed to construct a large steam plant on the Susquehanna River adjacent to the anthracite mines of Pennsylvania, utilize low-value anthracite (very nearly a waste product), and transmit the electric energy to Philadelphia, a transmission distance of about 150 miles.

However, a thorough investigation of the proposal proved that it would be very much more economical to locate the proposed steam plant at, or near, Philadelphia and ship the energy as coal over the rails to the plant. This kind of transmission, by which power is transmitted long distances without take-offs, might be termed "express transmission," and it is generally uneconomical except in the case of certain low-cost hydro-electric projects. This does not necessarily mean that long-distance transmission is uneconomical, however. Often, a minor load center reached by transmission could not alone support a large, low-cost, efficient steam plant, but several of these centers inter-connected may make such a plant economically advisable. There are also other factors which sometimes justify long-distance transmission as discussed by the writer (see text beginning "Reserve Capacity Savings Due to Inter-Connection").

---

[51] Cons. Engr., Philadelphia, Pa.

In considering the desirability of installing additional capacity, Mr. Sprague calls attention to the operating saving that may sometimes be effected through the installation of a new steam plant, and shows by an example that such an annual saving may sometimes cover a considerable part of the fixed charges on the new plant. The statement is correct, of course, but the weight that should be accorded to this factor is sometimes quite uncertain.

Thus, in the illustration given by Mr. Sprague, a new steam plant would operate at a capacity of 7 000 hr per yr, or on a capacity factor of 80 per cent. No steam plant operates for many years at such a high capacity factor. As shown by Mr. Samuels, the average annual capacity factor of all steam plants in the United States is about 34 per cent.

In an economic study for the purpose of determining the advisability of a capital expenditure for a new steam plant, erroneous conclusions may be reached by assuming a capacity factor of 80% as in Mr. Sprague's illustration. Although such a high capacity factor may rule for the first few years, experience indicates that the average annual capacity factor of the steam plant during its life is more likely to be something of the order of 35 per cent. Hence, such savings as those indicated by Mr. Sprague should, more properly, be considered as temporarily contributing to the carrying of the fixed charges on the plant until such time as the full capacity of the plant is required.

The foregoing is only one of the reasons why, in common with many other engineers, the writer finds it advisable, in economic investigations of this character, to make a study of the entire system, together with set-ups showing estimated results over a term of years in the future.

Based on the best available load predictions, the object is to arrange a program to meet the increasing load with increments of capacity in such a manner that the total annual operating cost (for power supply) plus annual fixed charges on new money is always at a minimum as compared to what it would be with any other plan of development. This is a "cut-and-try" method and is necessarily laborious. Conclusions thus arrived at are often at variance with short-cut methods of analysis, but are much more reliable. If load growth does not proceed as estimated, the soundness of the conclusions are not usually affected, as, generally, this merely means that the program is stepped back or accelerated, as the case may be, to meet the new load estimates.

Philip Sporn,[52] M. Am. Soc. C. E. (by letter).—It is interesting and gratifying that all the discussions are free from any great amount of "heat" and acrimony which prevail altogether too frequently in any discussion involving economics. For his own contribution to the Symposium, in particular, the writer anticipated much critical review because it dealt with that uncertainty —cost—and what is more controversial—comparative cost. He is particularly delighted, therefore, that the discussions are so generally commendatory, leaving so little to discuss in the closure.

---

[52] Vice-Pres. in Chg. of Eng., Am. Gas & Elec. Service Corporation, New York, N. Y.

The writer is not a partisan of either steam power or hydro power but he is an advocate of generating power in that manner which will be most economical and, therefore, in that manner which is certain to be most productive both from a social and from a business standpoint. During the five years since 1933 it has been assumed altogether too frequently that the former (that is, social benefit) could be obtained at the expense of the latter. The writer, however, does not believe that it can. If a situation to satisfy the true economic criteria demands hydro power, it should be used for that situation, but if the situation demands the use of steam power, the choice should be steam power. The writer makes this statement because underlying some of the discussions he detects a feeling (not openly expressed) that he has not been entirely impartial in his presentation and that he has, perhaps, "tipped the scales" in favor of steam power. This, of course, is not the case. Furthermore, the writer very definitely has refrained from adopting a regional viewpoint and has been unwilling to look at power as something that should be handled from a narrow viewpoint or from the viewpoint that what is locally available is of necessity the best simply because it is "on the spot." On the contrary, he has always considered as the basic outlook for the proper engineering and social economic solution of the power problem, the principle that, regardless of where in the country the fuel or the materials must come from, as long as they are within the boundaries of the United States, in the long run the national economy would best be served by using those materials and that equipment which result in the lowest cost power. For some time to come it may be very uneconomical to develop many hydro sites and, with the grave situation in which the soft coal industry finds itself, the national interest would best be served by adhering to steam power, provided steam power gives the net over-all lowest cost of power—and by that the writer does not mean cost after deducting any subsidies either of a direct or of an indirect nature.

Again, this means that the writer is perfectly willing to look with equanimity upon the immediate present loss of white coal or hydro power, but he does not consider that a loss in the true sense of the term; nor is it of any grave consequence, provided the national economy is better served by developing some other form of power even if that involves the burning of fuel.

Mr. Sprague's point regarding certain limitations and qualifications necessary to be considered in connection with the data presented in Fig. 34, on the relative costs of freight and electrical transmission of energy, are well taken and are generally understood by every engineer who has anything to do with the power problem. That is, it is well understood that any study of the type made as the basis for Fig. 34, of necessity, fails to give consideration to the distribution angle and that from a distribution standpoint the economics of short transmission distances become more favorable to the electrical side as against the freight side. Hence, in spite of the apparent better economics obtainable by freight for transmission distances even as short as 30 miles, the mean weighted distance of transmission on the inter-connected system of the American Gas and Electric Company is actually close to 60 miles under normal conditions.

However, Fig. 34 seems very much worth studying. Taking to heart the lessons it shows would obviate the bad effects of the large mass of misinformation propagated almost daily by those who should know better as regards the feasibility or economy of long-distance transmission. Thus, quoting from a United Press Dispatch as printed in the *New York World Telegram* of July 29, 1938:

> "Mr. Ross suggested that the Columbia River on the west coast might even supply electricity to New York, 3,000 miles away, and the Niagara or St. Lawrence Rivers might send electricity to homes in Florida or for irrigating the Southwest.
>
> "Mr. Ross expressed his ideas to the Engineers' Club of Seattle. He has made a special study, at the request of President Roosevelt, he said, of the possibilities of transmitting electricity from one part of the country to the other.
>
> "The results of such a system, Mr. Ross said, would be cheaper electricity, more abundant use of it and improved service to consumers. He said the price would be reduced because a purchaser now getting electricity from a distance of 100 miles could get it as cheaply from a distance of 1,000 miles.
>
> "Direct current transmission would be used between the major plants suggested by Mr. Ross, but the present alternating current system would not be disturbed."

The writer has followed very closely every major transmission development for the past twenty years and has been intimately associated with the expansion and development of the transmission art during that period. He has particularly followed at close range the work that has been done and that is being done in the development or the attempted development of direct-current transmission, and all that he can say in connection with any opinion that economical 1 000-mile or 3 000-mile transmission of power is imminent, is that it is pure "poppycock," and that on the whole does not warrant any serious lay, let alone engineering, consideration.

Mr. Samuels seems quite unhappy about the purported inaccurate use of some of the terms such as "load factor," "use factor," and "plant factor." The writer cannot help but agree with him, but he feels that it will be necessary to wait for a younger generation to grow up and be taught before any degree of perfection is possible. The writer does not agree that 15 yr should be considered the average life of a steam plant because he does not believe that any such conclusion would be correct even if statistics may make it appear so. For 20 yr (1918–1938), the power industry has grown very rapidly. As a matter of fact, until the depression that started in 1930, regardless of the changes in the business cycle, there never was a year in which the output of electric energy by utility industries was not greater than the preceding year's output. Changes in the art of steam power generation moved forward just as rapidly. This led to a very high rate of obsolescence on steam plants, both from inadequacy and change in the art, but more so from inadequacy than change in the art. To-day, the electric utility industry has definitely passed the period of very rapid growth and is subject to the same fluctuations of the business cycle almost to the same degree as other businesses; and, although the art of steam power generation is continuing to improve, the effects of obsolescence and inadequacy probably will not be such in the next 20 yr as to limit the plants that are now being built to a life of only 20 yr. As a matter of fact, many of the developments that have taken place during the past several years have been such as to arrest, definitely, the sharp obsolescent trend of plants built in the decade, 1916–1926. Therefore, the writer believes that Mr. Samuels' selection of 15 yr for the life of a steam plant is ultra-conservative.

Mr. Kramer takes exception to some of the statements in the paper with regard to the status that hydro-electric energy holds in the present power "picture" of the United States, and specifically points out that its position in the Northwestern States is better than would be indicated by the statements that hydro plants in general as a source of power, are out of the economic range. He may be correct as regards certain sections of the Northwest; but the writer does not believe he is right as regards California, and he is quite certain that Mr. Kramer is wrong as regards the Southeastern States. Furthermore, as regards the Northwest, the writer is not at all certain that if consideration is given to the definite static conditions of hydro developments (that is, to the fact that anticipated improvements in that field are almost negligible, whereas the improvements that can be looked forward to in the steam generation art are many), the economics would not be again in favor of steam generation. However, even if Mr. Kramer were correct, it is a fact that 70% of all the energy generated and used in the United States is produced in the area east of the Mississippi River, and the writer's statement, even in its full broadness, is definitely applicable to that region.

Mr. Kramer also takes issue with the use of 10.75% as a fixed-charge rate for hydro plants, and he shows a build-up whereby he gets a value of 6.87 per cent. Even disregarding the fact that there is no general agreement on this point (and the writer, definitely, does not agree to the basis followed by Mr. Kramer in building up his fixed charge of 6.87% by the use of the sinking-fund method of depreciation), there is the further fact that what is really important is the relative value of fixed charges. Mr. Kramer does not make clear that where the writer has used 10.75% as a fixed charge for hydro-electric power he has used a fixed charge of 12.75% for steam plants and that, if a charge of 6.87% is the proper one for hydro plants, then logically 8.87% would be the proper one to use for a steam plant.

Again, Mr. Kramer takes exception to the statements that the most economical sites were developed long ago and states that this is not true if applied to such developments as Boulder, Bonneville, or Grand Coulee, or to the undeveloped project on the St. Lawrence River. His conclusion is that in many cases such projects have not been undertaken heretofore on account of their size. This disregards the fact that one of the principal reasons that they have not been developed is that they are located such a distance from a market. There is much undeveloped hydro-energy in Alaska but, for the present, at least, it will have to remain undeveloped until local markets for it are found.

It cannot possibly be brought to market economically in the United States. There are many people who believe that much of the power that is now undergoing development is uneconomical power for the reason that the cost of bringing it to the market makes the combined delivered cost so much greater than power that could be generated within reasonable distances from the market.

A number of other points have been raised which the writer would like to discuss but space will not permit. They are so important and so technical that it would involve the preparation of a discussion of a length perhaps equal to some of the papers in the Symposium. For instance, Mr. Samuels quotes Mr. Knowlton as having recently presented in the *Electrical World* a tabulation of large plants from which it appears that, above a certain point, the saving in fuel brought about by a higher steam pressure is offset by higher fixed charges. This merits considerable discussion. There is the aspect, for example, that what is special practice as regards pressures and temperatures to-day, becomes standard practice five to ten years from the time such temperatures or pressures are first brought within a practical operating range. There are many other phases of this problem that need to be discussed. The discussion of subjects such as this one would be interesting and informative but probably would not add sufficiently to the value of the Symposium to warrant the time and the space. It may very well be apropos for discussion at some other point.

Note.—This Symposium was presented at the meeting of the Power Division, New York, N. Y., January 20, 1938, and published in April, 1938, *Proceedings*.

ELEMENTS OF COST

BY JOHN C. PAGE,[1] M. AM. SOC. C. E.

SYNOPSIS

In recent years the mere mention of the word, "power," especially when uttered by a Government official or used in connection with the word, "water," has been sufficient to send large groups of Americans into hysterics. As a result it has been difficult for any one to approach this subject calmly at a time when a calm approach is needed.

Modern civilization is founded on the utilization of power in a myriad of ways. Of the total energy used in the United States, that produced by water power has remained almost constant at between 3% and 4% for fifty years. The energy used to generate electricity for public utilities in 1936 amounted to less than one-tenth of the total derived that year from mineral fuels and water power. Stated in its true perspective in this manner, the importance of power supply for public utilities appears comparatively small.

There is nothing in the situation with respect to power that cannot be rationalized. When reduced to its elements, the power question resolves itself into simple terms. This paper is concerned with elements of power cost, and the writer submits that these elements, in themselves, are not complicated. Papers will follow which will deal more specifically with individual items of cost.

It should be borne in mind—and many writers on the subject have not consistently done so—that each power development or project is a problem in itself, and that it is unsafe to generalize broadly on the power theme. "Sauce for the goose" is not necessarily "sauce for the gander" in the power field. That method of power generation which is most economical, and which, therefore, should yield the greatest social values in one area, may be the most costly in another. In any locality, changing conditions also may make the method that was most economical yesterday more costly to-morrow. These facts are self-evident to the Engineering Profession, but they have not always been so treated.

The elements of cost of electric power fall naturally into two general groups: (1) Fixed charges which include interest and amortization, depreciation and obsolescence, taxes and insurance; and (2) operating expenses, which include fuel in the case of steam and Diesel generating plants, water, oil, and operating supplies, operators' wages, superintendence, maintenance and repairs, administration and legal expense, and miscellaneous expenses.

---

[1] Commr., U. S. Bureau of Reclamation, Washington, D. C.

The elements of cost of power are essentially the same whether produced by steam, Diesel, or hydro-electric plants, except the cost of fuel, but the extent to which the various elements enter into the cost varies widely. The purpose of this paper is to outline the elementary parts involved in the cost of producing electrical energy and to indicate how the total cost of energy can be affected.

Fixed Charges

Fixed charges depend primarily upon the investment cost of the various components of the power system, and they represent a very large part of the total cost of water power. In steam plants, however, the fixed charges represent a much smaller proportion of the total cost of power.

The capital cost of hydro-electric developments varies widely and depends on the physical characteristics of the site, such as topography and location, head, stream flow, storage requirements, right of way, etc. The capital cost of steam plants also varies through a considerable but fairly well established range and depends upon the type and capacity of the plant, location, kind of fuel, and fuel economy for which the plant is designed.

The rate of interest paid on the money invested in a power project varies from year to year, depending upon the condition of the money market. At present, both public and private agencies can borrow at from 3.5% to 4% per yr. A public agency usually finances its undertakings by the sale of bonds, and provision must be made for the retirement of the bonds as well as for payment of interest. Private company financing on the other hand is somewhat more involved; funds may be obtained by sale of bonds or by sale of stock, or by a combination of the two. The principal difference between the public and the private agencies in the matter of fixed charges is that the private company endeavors to secure a so-called fair rate of return on its investment, whereas the public agency is generally concerned only with interest and amortization of the capital investment.

Depreciation depends upon the useful life expectancy of the various features of the power development. The usual practice of both public and private power agencies is to provide a depreciation reserve fund for the purpose of replacing the various components of the power system. In the case of a public project financed entirely by sale of bonds which must be retired within, say, 30 or 40 yr, it is doubtful whether depreciation should be included in the features that will have a useful life far beyond the end of the amortization period of the bond. For instance, a large concrete dam, which is a major feature of a hydro-electric development, has a relatively long life and may reasonably be expected to be useful for 50 or 100 yr, or even longer. If depreciation charges are included in the cost of such a feature during the period that its cost is being amortized, it would in effect constitute a double repayment. It is necessary, however, to include sufficient depreciation to provide for replacement of those items which will have to be replaced during the amortization period. Although a dam may have a useful life expectancy in excess of the amortization period, it may be equipped with gates and other mechanical equipment which will have a much shorter life, and will have to be replaced during the amortization period.

The useful life expectancy of different features of a power system varies considerably. For example, a steam-generating station may have a life expectancy of, say, 30 yr, whereas a hydro-electric plant may have a life expectancy of from 50 to 75 yr. The machinery and equipment in a steam plant operate at relatively high speed and at high temperature; hydro-electric plant equipment operates at slow speed and at much lower temperatures. It is customary, therefore, to assume a higher rate of depreciation for a steam plant than for a hydro-electric plant. Similarly, for other features of a power system, the depreciation in each unit should be based on the best estimate of its probable useful life.

Taxes are an important item in the total fixed charges of a private power company, and they vary considerably in different localities. A public power development on the other hand is usually exempt from taxation. In certain instances, publicly owned power systems have voluntarily included taxes in the rate base, and this seems to be desirable practice. A private power company usually must pay for franchises permitting it to operate, and it must also pay State and Federal income taxes. The public agency is not normally burdened with such charges. In general, the fixed charges are considerably higher for a private than for a public power agency.

OPERATING EXPENSES

The cost of operating hydro-electric plants is a relatively small part of the total cost of power generation, and is practically independent of the plant output. The operation costs of steam-electric plants differ markedly from those of hydro-electric plants. The cost of fuel is the major factor in the cost of operating steam plants, and the quantity of fuel consumed varies with the energy output of the plant.

Operating expenses consist principally of operators' wages, oil, operating supplies, maintenance and repairs, and fuel in the case of heat-generated energy. Fuel costs vary materially due to location, distance from source of supply, method of transportation, and competition between fuels; and the cost of a given fuel may fluctuate from year to year. Many modern steam plants are designed to burn two kinds of fuel, such as coal and oil, or natural gas and oil. This arrangement makes it possible to take advantage of the competitive situation and use whichever fuel may be cheaper at the moment. In rare instances, natural gas can be purchased at low prices during periods when surplus gas is available. Some contracts for natural gas have been made on an off-peak basis, with the supplying agency reserving the right to discontinue delivery during periods when the full capacity of its pipe line is required to supply customers other than the power plant. Under such a contract, the steam plant can take advantage of the cheap natural gas when available, but must resort to a higher priced fuel at times when natural gas is not available.

There has been a gradual improvement in the fuel economy of steam plants, due to the use of larger generating units, higher steam pressures, and higher steam temperatures; and it is now possible, with a modern steam plant designed for high economy, with units of 50 000-kw capacity, or larger, to secure a fuel economy equivalent to 11 000 Btu per net kw-hr.

Station-service requirements generally range from 4% to 10% of the installed capacity. A steam plant will require considerably more power for station service than a hydro-electric plant of comparable size, because of the necessity for operating cooling water pumps, boiler-feed water pumps, coal-handling equipment, etc.

Effect of Load Factor

The energy output of a given power plant will vary directly with the load factor or the plant capacity factor at which the plant is operated. Stated in another way, in order to produce a given quantity of energy the installed generating capacity must be increased as the load factor is reduced.

The effect of plant capacity factor on the cost of power is particularly marked in the case of hydro-electric plants because the annual cost of these plants is fixed and is practically independent of the plant output. The cost of energy generated at a particular hydro-electric plant may be 4 mills per kw-hr if the plant is operated at 80% load factor; but if it is operated at only 40% load factor, it will produce only one-half as much energy and the cost will be increased to 8 mills per kw-hr. In the case of steam-electric plants the load factor has a decided effect on the cost of power although it is not quite so pronounced. The cost of fuel represents a large part of the cost of operating a steam plant and the quantity of fuel consumed varies with the plant output. The cost of production at a particular steam-electric plant may be 4 mills per kw-hr if the plant is operated at a load factor of 80%, whereas if the same plant is operated at only 40% load factor the cost of energy may be increased only to 6 mills per kw-hr.

Effect of Power Factor

The current to be carried by the electrical equipment depends upon the power factor. If the power factor is low, additional carrying capacity must be provided in the generators, buses, transformers, circuit breakers, and transmission lines, thus increasing the cost of this equipment and increasing the cost of power. This is usually not of great importance in the case of hydro-electric developments having long-distance, high-voltage transmission lines because such lines inherently have considerable electrical capacity which tends to correct the low power factor of the load. Under these conditions the hydro-electric plant usually operates at a reasonably high power factor. Steam plants near the load center, on the other hand, do not have the advantage of the corrective effect of long-distance transmission lines, and the electrical equipment in these plants must be capable of carrying the increased current resulting from low power factor, or synchronous condensers must be provided to correct the condition.

Quality of Power Service

Certain classes of power users are much more exacting as to the quality of power service than others; for example, a metropolitan area demands service as nearly as possible free from power outages. For these areas the speed must be maintained within very close limits and the voltage must be closely regulated. On the other hand, occasional momentary outages and minor fluctuations in speed and voltage may not be of serious consequence in small communities or to isolated industrial users. The extent to which a power system is designed to insure continuity of service, close regulation of speed, and voltage, is reflected in the cost of power. As an example, the City of Los Angeles, Calif., obtains the major part of its power supply from the Boulder Power Plant, and its service requirements are most exacting. The transmission circuits are designed to be lightning proof which necessitated large expense for overhead ground wires, counterpoises, etc. Special characteristics, such as extra fly-wheel effect for low reactance and high short-circuit ratio, are incorporated in the generators to insure system stability under transmission-fault conditions. Exceptionally high-speed oil-circuit breakers, functioning in less than three cycles, are required to isolate a section of the transmission line on which a fault may occur before service to customers is affected. Special devices and equipment to control accurately the frequency and voltage are provided. All these refinements are necessary to provide the high standard of service demanded by a metropolitan area.

Another block of Boulder power is used by the Metropolitan Water District of Southern California for pumping water through its aqueduct, and in this case the service requirements are much less exacting. The District can tolerate occasional brief outages since they involve only a temporary shut-down of the pumps which can be re-started readily as soon as power service is restored. The cost of the District's transmission lines and generating equipment is considerably less than that of the City of Los Angeles because of the difference in quality of service demanded by the different classes of loads.

Spare generating equipment is an essential part of every power system. It is necessary to have sufficient spare capacity so that equipment can be taken out of service for inspection, maintenance, and repair, without interfering with delivery of power. The minimum amount of spare capacity must be adequate to permit the largest single generating unit on the system to be taken out of service. The element of dependability of the various sources of power must be considered carefully in determining the required amount of spare capacity. In general, the dependability of hydro-electric generating units is substantially greater than that of steam units, due to the fact that the former operate at comparatively slow speed and at ordinary temperatures, whereas the steam units operate at very high speed and at high temperatures.

COST OF TRANSMISSION

Generating stations must necessarily be located where conditions are suitable. A steam plant must have an adequate supply of cooling water for condensing purposes, and must be situated where transportation facilities are available for delivering fuel economically; and a hydro-electric plant must be located where water and head are available. Transmission facilities are necessary for transmitting the power from the point at which it is generated to the load centers, and the cost of transmission is an important item in the total cost of power delivered at such load centers. In the case of a hydro-electric development situated remote from the load center, the cost of transmission may be as great as, or greater than, the cost of generation.

The output of the generating station must be delivered to the transmission lines at their operating voltage and this necessitates step-up transformers and high-voltage switching and protective equipment at the generating station. The cost of the transforming and high-voltage switching equipment at the generating end of the transmission line is usually dependent largely upon the voltage of the lines and is independent of the distance of transmission.

Provision must be made for transmission-line outages, either by duplicate circuits or by stand-by generating capacity at the terminal end. If the transmission lines are designed and built in accordance with the best modern practice, such outages are infrequent.

The cost of power transmission depends principally upon the length, voltage, and capacity of the line, and upon the load factor at which the line is operated. The annual costs of a particular transmission system are practically fixed and are independent of the amount of energy transmitted; and, as in the case of hydro-electric plants, the higher the load factor the lower will be the cost of transmission. The over-all efficiency of transmission, including the voltage transformation under generating and receiving ends, should generally be better than 90 per cent.

The distance from a power development to a market is another factor that affects the cost of power. The greater the distance the greater the cost of transmission, and although a development in itself may be exceptionally low in cost per unit of capacity, it may require so large an investment in transmission lines to reach a market that the power cannot be delivered in competition with power from other sources. On the other hand, a relatively large investment per unit of capacity may be warranted in a plant situated close to a load center and requiring small investment in transmission facilities.

INTER-CONNECTIONS

Power supplies in the United States have developed from the steam engine or water-wheel supplying an individual mill or factory to the central station supplying a community; and then to the power system with a combination of steam and hydro-electric generating stations supplying power to a large territory; and, finally, to the inter-connection of power systems which makes it possible to centralize the generation of steam power at advantageous points where fuel and water for condensing purposes are readily obtainable, and to use large capacity and highly efficient generating units. These large generating plants connected by, and feeding power into, a large transmission system or network, make it possible to take advantage of diversity between the different loads on the system, minimize the stand-by capacity and spare equipment required to insure continuity of service, and secure high plant capacity factor and high fuel economy. It also makes it economically feasible to develop large-capacity hydro-electric projects and to utilize large amounts of low-cost, secondary, or seasonal hydro-electric energy which otherwise would be wasted. Inter-connection of power systems has played an important part in reducing the cost of power.

Many large power systems are supplied by a combination of hydro-electric power and steam. Steam plants are the more economical for supplying peak-load capacity due to their low investment cost per unit of capacity, whereas the hydro-electric plant may be the more economical for supplying the energy requirements of the system, notwithstanding their higher cost per unit of capacity due to their low operating cost. Normally, the hydro-electric plants are operated so as to generate the maximum energy and the steam plants are used to supply the system peak-load requirements with a minimum of fuel consumption. During periods of subnormal water supply, however, normal operating procedure may be reversed and the steam plants may be operated on base load at high-load factor to supply the deficiency in energy output of the hydro-electric plants whereas the latter are used to supply system peak-load requirements. Thus, the two sources of power supplement each other and although the total investment in generating capacity required to supply a given system peak may be greater with a combination of steam and hydro-electric than with steam alone, nevertheless, the combination results in cheaper power, especially where large quantities of low-cost secondary or seasonal hydro-electric energy can be utilized in lieu of steam-generated energy.

Market for Power

The market for power and the length of time required to absorb the power output must be carefully considered in determining the economic feasibility of a power development. This is particularly important in the case of large hydro-electric developments involving large initial capital outlay. The major part of the cost of a hydro-electric development is in the dam, storage reservoir, power-house, etc., which must be constructed before power can be produced. The annual cost of such a project may be in excess of the annual revenues for several years until a large part of the available power can be disposed of, and deficits will accumulate. The deficits accumulated during the early years may make the project economically infeasible.

Large Federal Multiple-Purpose Projects

In recent years, a number of large multiple-purpose projects, involving flood control, improvement of navigation, storage of water for irrigation and domestic purposes, silt storage, prevention of encroachment of salt water into fresh-water supplies, and power development have been undertaken by the Federal Government. These are essentially conservation projects of national scope and the power which they make available, although important from the standpoint of defraying part or all of the cost of these projects, is incidental and subordinate to the other more vital functions. These projects are too large and require too much capital outlay to be economically feasible for development by private enterprise.

The cost of power at these multiple-purpose projects depends largely upon the allocation of the cost to the various functions served. For instance, the primary purposes of the Boulder Canyon Project are to regulate the Colorado River in the interests of navigation; to provide flood protection for the Lower Colorado River Valley, including the rich Imperial Valley in Southern California, and to conserve the flood waters which otherwise would be wasted into the Gulf of California to make them available for irrigation and domestic uses. It seems appropriate to allocate part of the cost of Boulder Dam to items of major Federal interest, and Congress recognized the primary purposes of the project by providing that $25 000 000 of the cost of the project should be allocated to flood control to be repaid out of surplus revenues if any accrue.

The Bonneville Project on the Lower Columbia River serves to improve navigation as well as to produce hydro-electric power, and the Federal Power Commission is now (1938) considering the proper allocation of the cost of this project as between navigation and power. The Grand Coulee Project on the Upper Columbia River is primarily a conservation project which will provide water for the irrigation of about 1 200 000 acres of land in the Columbia Basin. The reservoir created by Grand Coulee Dam will afford some measure of flood control, will improve navigation, and will greatly increase the low-flow power output of the present and prospective power developments on the Columbia River below that point. The proper allocation of the cost of Grand Coulee Dam as between the various functions it serves, should be considered at the proper time, and the cost of power should be established on the basis of the allocation finally adopted. The Shasta Dam on the Upper Sacramento River in Northern California is another of the large Federal projects. It involves flood control, navigation improvement, salinity control, conservation of flood waters for irrigation and domestic uses, and, incidentally, the development of a large block of power. Here, again, a proper allocation of the cost of the project to the various functions it serves will be necessary in determining the cost of power.

It is useless to argue that the Federal Government should not build projects of this type because they also generate power. Social considerations demand their construction and also demand their full utilization, as well, so that the potential energy they create must be developed and made available for use.

One hears of social and of human engineers. The terms are of little moment. More important is the need for realization by the profession, of the kinship between engineering activities, as such, and the progress of an industrial, a power, civilization. Too few engineers have included in their activities a broad consideration of the social and economic objectives of the major problems upon which they have been called to work. Pre-eminent in the technical fields, all have not yet seized the opportunity to apply their abilities on the broader front.

Thought on the subject of power ranges from that of the evangelist who believes that power should be made as free as air, to that of the tycoon who views power as the silver spoon meant for the mouths of those born to the economic purple. As a professional man, the engineer has spent much of his time with the formulas of the power industry, but has devoted too little of his thought to the implications, social and otherwise, of what he has wrought. Has not the time come for the engineer to apply more of his effort to the determination of a sound basis for the settlement of the power question?

If the profession accepts, as it must, the idea that such great projects as Bonneville, Boulder, Grand Coulee, Shasta, and other dams must be built, has not the time come for the Engineering Profession to approach them calmly so as to appraise their benefits soundly both as power projects and as conservation projects?

Public agencies have demonstrated, in many localities, that they can manufacture and distribute power efficiently and successfully with public benefits. Privately owned utilities have served as admirably in many other localities. Each power project is a separate problem; because one method has rendered better service in one instance is not conclusive proof that another will not render better service elsewhere. Remembering these facts, has not the time arrived for the Engineering Profession: (1) To concede that inherently there is nothing bad in either public or private ownership of electrical utilities; (2) to accept the fact that either must earn its right to continued existence in any locality by efficient service in the public interest; (3) to lay aside prejudices; and (4) to apply itself with the precise tools it has available in technical and scientific knowledge to the job of solving the power problem?

The electrical industry is monopolistic by nature. It is self-evident that, in a democracy, a monopoly can be tolerated only as long as the people feel that it serves in the public interest. Is it not time, then, for engineers, who play so prominent a rôle in the field of power, to assist, honestly and wholeheartedly, in seeing to it that the public weal is placed foremost among the objectives of the power industry?

HEAT-GENERATED ENERGY

BY C. F. HIRSHFELD,[2] ESQ., AND R. M. VAN DUZER, JR.,[3] ESQ.

SYNOPSIS

This paper is devoted to the cost of producing electric power in fuel-burning plant. It is divided roughly into five parts: The first covers the definition of cost as used herein and certain factors affecting the cost; the second treats cost of steam-electric generation; the third refers briefly to the performance and possibilities of binary vapor cycles, with particular reference to the mercury vapor type; the fourth is devoted to cost of Diesel plant generation; and the fifth contains a very brief reference to future possibilities. Power cost, as used herein, refers to the total of operating, fixed charge, and general overhead expense at the point of generation.

INTRODUCTION

When one speaks or writes of cost it is necessary to be very specific if one's statements are to have more than general significance. Whether reference is made to commodity or service, the expression, "cost," is meaningless unless many characteristics of an actual or assumed transaction are given. Thus, if one refers to the cost of apples, one may have reference to the cost of production in a given orchard in a given year, or to the average cost of production throughout a section or over the entire country. Such a person may have reference to the wholesale or retail price at a given time and place; he may have reference to the export price at a given time and place; and so on through a great many possibilities. It is obvious that the cost under any or all of the mentioned conditions, and others, may properly be spoken of as the cost of apples, and it is equally obvious that all such costs might be different at exactly the same time.

The cost of power is an equally flexible expression. It may refer to production cost at the point of generation with or without allowance for power used in the production process. It may mean either of these limitations, enlarged by any number of other charges, such as supervision by staff members, taxes, an allowance of some kind for physical or some other form of depreciation, interest on the investment in production facilities, etc.; or it may mean cost to the producer in any of these forms at a point remote from the place of generation, as, for example, at the end of a transmission line at transmission-line voltage, or at some lower voltage. On the other hand, it may mean cost to the producer in any one of a great number of forms at some point or points in a distribution system; or it may mean cost to the consumer, including not only the total cost of the actual power to the producer at the point of delivery, but also the cost of meter reading and billing, the cost of any services other than pure power supply, a proper share of general costs of several varieties, and profit, if there is any.

---

[2] Chf. of Research, The Detroit Edison Co., Detroit, Mich. Mr. Hirshfeld died April 19, 1939.

[3] Engr., The Detroit Edison Co., Detroit, Mich.

In view of such a multitude of possible meanings of the title of this paper, and in view of the resulting danger of fallacious comparisons and inferences, it is deemed necessary to define the sense in which cost of power is used herein. The expression is used to designate the total cost of power to the producer at the point of generation and ready for delivery to the transmission or distribution system which is to convey it elsewhere. By total cost is meant not only the cost of labor and fuel and other supplies, but also all supervision, all allowances for depreciation, taxes, and all other forms of overhead expanse. This may be called the "total power plant cost," or the "total cost at the power plant." The significance of the word, "total," should not be forgotten. Attention is called to the fact that cost as used herein is in terms of net output, not total generation; that is, the unit cost is determined by dividing the total cost, as defined, by that number of kilowatt-hours delivered to the line and available for transmission or distribution as the case may be.

For the benefit of those who are not familiar with the facts and economics of power supply, it is desirable to emphasize the fact that the cost of power as defined herein may represent legitimately either a very large part or a very small part of the cost to the ultimate consumer. For example, if a fuel-burning power plant is considered, which is situated in a manufacturing establishment of small extent, and is supplying all its output to that establishment, transmission costs are not involved, distribution costs are small, meter reading and billing are not necessary, and no kind of service other than power supply is given. Under such circumstances the total power-plant cost, as defined herein, represents practically the entire cost to the consumer. If, however, the power must be transmitted at high voltage to a considerable distance and there sold wholesale to a community, the power-plant cost must obviously be increased by all transmission costs, including losses, operating expenses, and fixed charges, and by the profit, in order to obtain the cost to the ultimate consumer. Neglecting the item of profit, it is quite possible for the legitimate cost of delivery at the wholesaling point to equal one and one-half times, or more, the total cost of the power plant. Furthermore, if the power is to be retailed over a wide area, even near the power plant, it is quite possible for a legitimate cost to the consumer to equal seven or eight times the power-plant cost and to vary widely each side of these values depending upon the density and character of load, the character of the territory, the kind of service rendered, etc. It is obvious that mere power-plant cost tells a very small part of the entire story and that many fallacious conclusions may be drawn with respect to power cost under different conditions if this fact is not fully appreciated.

A presentation of the data indicated by the title of this paper would be simple indeed if it were true that the total power plant cost of fuel-generated power were the same every where, or under all conditions, or even at a given fuel cost. No such simple relations exist; the cost of fuel-generated power is uniquely different for different conditioning factors. Moreover, it is practically impossible to predict how these conditioning factors will combine in any case until a specifically detailed study has been made for that case. If one is to consider such power costs in any general manner it must be done in terms of cost ranges instead of in terms of specific costs. This method has been adopted in the paper.

As stated previously, the total plant cost of power is made up of a number of cost items, a complete list, divided under three convenient and conventional headings, is as follows:

(*1*) *Operating Costs:* Fuel; operating labor; water; miscellaneous supplies and expenses; maintenance (labor and materials); and superintendence, clerical and testing.

(*2*) *Fixed Charge Expense:* Charge for depreciation; cost of money (interest, dividends, etc.); property taxes; and insurance (fire, casualty, liability, etc.).

(*3*) *General Over-Head Expense of Which Parts Should Be Allocated to Power Production:* Staff superintendence; staff accounting; general offices; stores and warehouses; transportation and communication; general and coal-testing laboratories; shops; working capital; regulatory commission expense; public injuries and damages; employee compensation insurance; social security tax; general taxes (income, surplus, sales, excise, franchise, corporation, etc.); legal and miscellaneous general expense.

Nearly every item in this long list does exist as an item of cost in any fuel-power production undertaking. Certain of them may be masked or may be "lumped in" with others so that their identities are lost, but they exist nevertheless. In small operations, laboratory expense undoubtedly would be absent. In private undertakings, such as industrial power plants as opposed to public utility activities, regulatory commission expense would not exist. With such limited exceptions, however, all the items have their equivalent in any production of power from fuel although their existence may not be appreciated and may not be shown by the method of accounting in use.

A mere survey of this list of components of total cost indicates the impracticability of treating every item in a paper of moderate length. Attention must be concentrated on the more important and larger components. Those that are slighted may conveniently be grouped into a percentage loading on others, or handled in some equally simple fashion; but their existence should not be overlooked. Furthermore, it is convenient to treat the steam and the internal combustion methods of power production separately. If this is not done the treatment becomes undesirably complex and difficult to follow.

Steam Power Costs

The methods used for producing power from steam are numerous. They all have in common the use of fuel-fired steam boilers which supply steam to prime movers of some kind; and that is about all they have in common. In general, when one refers to a steam-operated power plant, one visualizes the highly developed, condensing, steam-turbine, type of plant used in nearly all central stations and in many industrial plants. It must be remembered, however, that such plants represent only one of many classes; for example, the steam locomotives of the United States use a large part of the total fuel consumption and are just as truly steam power plants as the most elaborate central stations. Many industries use steam engines or steam turbines as devices by means of which to skim a certain amount of power from a steam supply required for process purposes. In such cases the major part of the heat originally in the fuel may legitimately be charged to process steam so that the fuel cost of the power may be reduced to comparatively low values. Similarly, under such conditions it is frequently legitimate to charge a large part of the cost of steam-producing equipment to process steam, thus diminishing the fixed charges against power.

Obviously, no paper of reasonable length could attempt to cover all such possibilities. After considerable thought the writers have decided to limit this section to the costs of fuel-generated power produced in condensing steam-turbine stations of what may be called the central station type. This type represents the nation's best achievement in the production of power as a commodity as cheaply as is compatible with reasonable continuity of supply. In adopting this course it seems wise not to neglect realities and, therefore, not to limit the treatment to the most economical central station that can be built to-day. The fact is that central station supply is now an old industry which of necessity carries with it those of the physical constructions incident to its growth which sound economics or the laws and regulations under which it operates have not yet required or permitted it to retire. An idealist might like to see everything but the latest and best retired over night. A realist takes cognizance of the fact that economic considerations do not permit this.

The fact is that the cost of steam-generated power from central stations is a composite of the cost obtained with plants of varying ages and, therefore, representing different stages in the development of the art. Naturally, each property utilizes its most economical equipment to the greatest practicable extent, but there are many limitations made necessary by physical and other factors that must not be ignored.

The writers have attempted to give a reasonably fair "picture" by considering the performances to be expected of plants operating at different steam pressures and steam temperatures, choosing the values so as to cover the entire field as it is found to-day. This has resulted in the choice of the following steam conditions:

Pressure, in pounds per square inch	Temperature, in degrees Fahrenheit
225	650
400	750
600	825
800	910
1 250	925

The values listed are to be regarded as nominal; that is, indicative of the general range in which actual values will be found. For example, 225 lb may represent any value between, say, 175 and 250 lb, whereas 650° F may represent any value between 550 and possibly 675 degrees.

It is also to be noted that no fixed and definitely predictable thermal performance can be assigned to any single combination of steam pressure and temperature. For one thing, there has been an ever-continuing development of power-plant equipment and power-plant design, so that the possibilities realizable from the use of a given steam condition have changed almost from year to year. Conditions and circumstances associated with different installations result in designing for different performances from what superficially looks like similar equipment, in order to obtain the best economic balances in different cases. Therefore, in presenting the performances from which costs may be calculated, it is necessary to use bands or ranges rather than exactly fixed or unique values.

The very marked effect of condenser vacuum upon the thermal performance of a steam-turbine plant is now generally well known. The attainable vacuum in any location is determined both by the quantity and the temperature of available circulating water and, to some extent, by its quality. In any general study of the type under discussion it is necessary, therefore, to take account in some way of the effect of average attainable vacuum. This has been done by considering a range covering the generally existing values.

It is not so commonly appreciated that the character of the load has a very marked effect upon attainable thermal and economic performances. This is a fact, however, and one fraught with complexities. Each physical unit concerned has a certain characteristic which may be defined as performance *versus* load. In general, the best thermal performance of the assembly of physical units constituting a power plant is attained near what is known as rated load, although this may be modified through rather wide limits at the time of design. Therefore, operation for long periods of time at lower rates of output must of necessity reduce the thermal performance.

This sounds, and is, simple; but it is by no means the whole story. The manner in which the load varies may be of greater significance than its average value over a given period. For example, two plants of like capacity might operate under such conditions that both of them produced in a given time, say, 24 hr, the same number of units of output. One might be operating under such conditions that it carried a perfectly uniform load throughout the 24-hr period, whereas the other produced all, or substantially all, of its output in, say, 9 hr. The characteristics of steam power plants are such that with other factors reasonably equal, the thermal performance of the steadily loaded plant might be appreciably better than that of the other. These are extreme assumptions with respect to central station operation but might be approached rather closely in industrial plants.

Another significant type of variation concerns the size of the load from minute to minute. If there is great fluctuation, the thermal performance is necessarily poorer than it would be if the same total output were produced under more nearly constant conditions. Variation from day to day is also of importance; for example, a plant may be heavily loaded during four or five days of the week and lightly loaded, or actually idle, during the remaining days. These variations and many others affect the initial design of the plant to the extent to which they can be foreseen; but, irrespective of the provisions that may be made in this direction, they affect both the thermal and the economic performance of the plant as it is operated.

Obviously, a given investment will be used to the best advantage with respect to unit fixed charges when the maximum number of units of product is produced. Moreover, a load characterized by high, short-time peaks must necessarily involve a greater investment in plant than one totaling the same number of units of output produced at more nearly a constant rate. It is evident, therefore, that the character of the load must affect the economic as well as the thermal performance.

Power engineers endeavor to express the significant characteristics of load by the use of a number of ratios known as factors. Thus, they use load factor, power factor, use factor, capacity factor, and others. Each has value and each tells something about the load; however, all combined, they still leave much of importance undisclosed. In any such general study as herein intended, it is not practicable to show completely the effects of all the possible characteristics of load. This is sufficiently difficult even in the study of an isolated case, and makes it almost impossible to compare fairly the performances obtained in as few as two isolated cases.

Under the circumstances the writers have had to content themselves with the use of one factor which may be regarded as the most general in character. By virtue of its generality it is correspondingly lacking in definitiveness. The criterion used is the annual capacity factor, or plant factor, which measures the actual output against what it would have been had the plant operated at full rated output throughout the year. This definition requires explanation. There can be little argument as to the actual annual output in any given case; but there are many different but accepted ways of computing what the output would have been had the plant operated at full capacity throughout the year. As used herein, it is assumed that steam generator capacity, prime mover capacity, and electric generator capacity, together with the capacity of all auxiliary equipment, are so well balanced that nothing prevents the operation of the main generators at full rated capacity indefinitely. The maximum possible output that is used in calculating the annual capacity factor is then based on the theoretical operation of the main generators at full rated capacity throughout the year.

In a continuing sense this maximum possible output is an unattainable performance in any real case, even if the load permitted. Equipment does wear out, maintenance must be performed, and occasional breakdowns of major character do occur. Therefore, the annual capacity factor as used herein is, in a sense, theoretical although it does have the value of being exact and relatively easily determined. In actual cases it always falls well below unity or 100%, depending upon the form in which one chooses to express the ratio.

The range used herein extends from 20 to 80 per cent. Old plants that are used only for peak and stand-by service may show an annual capacity factor well below 20%, or even below 10 per cent. When such low values are reached thermal performance is of little significance and power costs from such plants are too erratic to have much meaning in a paper of this kind, although they may have very great significance as constituting part of the power cost of a larger system. Few fuel-burning plants attain an annual capacity factor, as herein defined, in excess of 80 per cent. Even industrial plants that operate at practically full load for 24 hr per day seldom achieve such a value for any extended period. If a plant operated at full rated capacity 300 days per yr and was completely idle during the remaining days its annual capacity factor would be only about 82 per cent.

In the foregoing discussion of capacity factor, reference was made to the rated capacity of the plant. It is obvious that this must have a fairly exact value in any given case if the calculated value of capacity factor is to be properly significant. However, there are other considerations connected with capacity which may be treated in a rougher or more approximate fashion. For such purposes one may refer merely to the size of the plant, or to its capacity, meaning by that something of the order of, say, 100 000 kw instead of 25 000 kw or 300 000 kw.

Size, in this sense, has a most complicated effect upon power cost. In general, it may be stated that total power cost tends to decrease as the size of the plant is increased. This follows from many considerations such as the possible use of larger units with better thermal performance and smaller unit investment, from fewer man-hours per unit of output, and other favorable factors; the economic justification of ultra refinements of various kinds; the spreading of clerical and superintendence charges over a greater output, etc. So many apparent contradictions can be found, however, that it is not safe to assume that cost of power from a larger plant in one location will necessarily be lower than that from a smaller plant in another location. For example, a small plant may be constructed under conditions that justify the designer in planning for high economy, in making no provision for future enlargement, and in providing a minimum of spare capacity because of stand-by service from a transmission line of large capacity. If cost of power from such an installation is compared with that from a larger plant, in which costly provision has been made for relatively great expansion at some future time, and in which several relatively small units have been used to fit best to an existing load curve and supply adequate reserve capacity, it may well be that for some time the thermal, the labor, and the economic performances of the smaller plant will be better than those of the larger plant, all other things being equal. Many examples of other types might be cited as evidence of the danger of carrying a generalization too far.

For convenience, the writers have assumed plants of 150 000 to 250 000 kw in preparing the numerical data that follow. This statement means they have assumed a well balanced plant capable of delivering energy at such a rate when all equipment is available. No assumptions have been made with respect to the nominal rating of the plant because this is too complicated a consideration for general treatment. It involves choice of the size of units and many other choices that can be made only for known and reasonably specific conditions. Instead, they have lumped such variations of power costs as would occur by virtue of different causes into the margins provided by the use of ranges or upper and lower limits of costs of different types.

It is convenient to consider the different plants in the order of ascending pressures. The nominal 225-lb installation, therefore, is selected as the point of beginning. Practically all such plants of any magnitude which to-day are used for central station purposes are twenty years old or more. Therefore, they represent a comparatively early development of the art as it is now known. Just what they are capable of, with respect to thermal performance, depends upon the stage of development represented at the time of their construction and upon the changes that have been made since then, either by the improvement or replacement of existing equipment, or by the addition of new equipment.

Several curves showing thermal performances as derived from actual performance data obtained from a number of such plants, are shown in Fig. 1. The hatched area between Curves *a* and *b* indicates the probable range of thermal values for plants representing average conditions, such as typical central station load characteristics, reasonably good grades of eastern or mid-western bituminous coals, units of 20 000 kw, or larger, some modernization since initial installations, etc. Attention is called to the fact that values are all in terms of 1 in., Hg, back pressure. Practically all such plants of which the writers have knowledge are operated at comparatively low capacity factors, some as low as 10% and few as high as 40 per cent. The region beyond 40% is obtained largely by extrapolation and it is questionable in character for two reasons: (1) It is probable that many of the actual plants could not be operated continuously for the long periods of time at the outputs required to give the very high capacity factors, in spite of the fact that they frequently carry full load for shorter periods of time as required to meet the demands of the system; and, (2) the methods of extrapolation may not be very accurate.

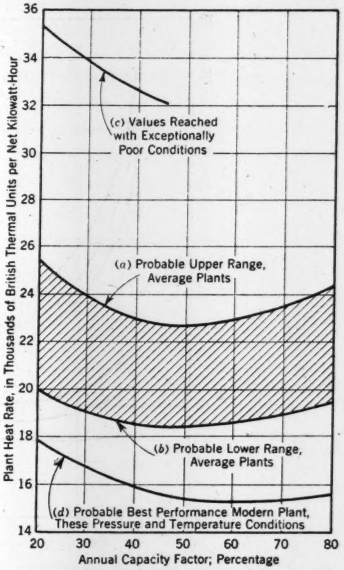

Fig. 1.—Thermal Performance of a Steam Plant; Nominal Pressure, 225 Pounds per Square Inch; 650 Degrees Fahrenheit and a Back Pressure of 1 Inch of Mercury

Curve *c* in Fig. 1 is introduced to show what may happen under abnormal conditions, such as unusual types of load, very poor or greatly varying fuel characteristics, little or no modernization, etc. The values shown on this curve have not been used in later computations and are included here only to indicate the danger of generalizing to too great an extent in such matters.

Curve *d* represents the probable performance of a plant built for these steam conditions at the present time; that is, a plant designed according to the present status of the art. It is of interest only as indicating the progress which has been made in improving thermal efficiency without reference to the effects of increased steam pressure and temperature. It is not probable that any large plant would now be built with these steam conditions, although exceptionally cheap fuel or other unique conditions might justify such a choice.

Group 1.—Fuel Costs.—The thermal performances as shown in Fig. 1 can be translated easily to fuel costs as soon as the cost of fuel is known. For the purposes of this paper, the writers have chosen to use a fuel cost at the plant of 15 cents per million Btu. This corresponds roughly to eastern bituminous coal of good grade at $4 per ton. It will become evident subsequently that correction for other fuel prices can be made easily. Curves *e* in Fig. 2 (*a*) and 2 (*b*) result from converting Curves *a* and *b* of Fig. 1, into fuel cost in mills per net kilowatt-hour. The method is obvious. It must be remembered that this limits the direct applicability of Curves *e* to 1 in., Hg, back pressure. However, methods of correcting to other pressures are given subsequently herein.

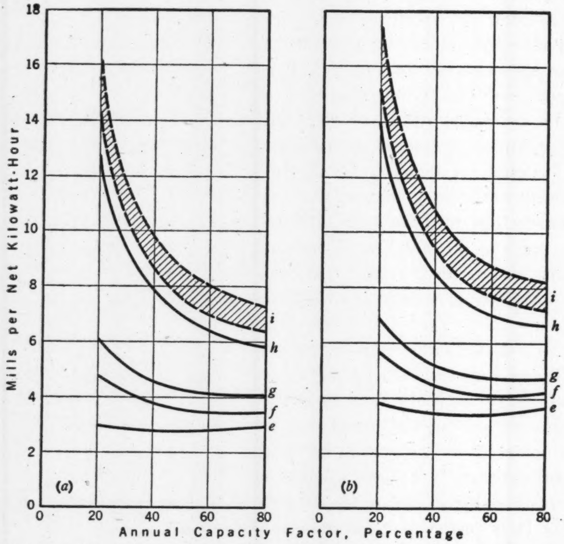

FIG. 2.—AVERAGE LOWER (*a*) AND UPPER (*b*) RANGES OF POWER COST FOR A STEAM PLANT; NOMINAL PRESSURE, 225 POUNDS PER SQUARE INCH; 650 DEGREES FAHRENHEIT; AND 1 INCH, HG, BACK PRESSURE

Operating Labor.—The next cost item listed under operating costs is that of operating labor, in which case two major variables must be considered: (1) The output per man-hour as determined by the efficiency of labor, the type of fuel, and the design of the plant; and (2) the average wage paid. This wage varies widely with geographical location, with type of community, and with other factors.

The output per man-hour for the nominal 225-lb plant has been assumed as shown by the full line in Fig. 3. It is applicable to plants burning the better grades of solid fuel and reasonably accurate to a capacity factor of 50 per cent. Below 50%, the performance of most of these plants will fall within ± 30% of the values indicated, as shown by the two dotted lines. Above 50% much will depend upon the character of the plant, if indeed it can be operated to produce higher capacity factors. As most plants actually are, it is probable that at higher capacity factors the slope of the full line would gradually become less as shown by the dotted extension, indicating increasingly less effective use of men. The same phenomenon would probably occur to an increased extent in plants having the poorer grades of solid fuel. For plants burning liquid and gaseous fuels, the net output per man-hour at any load factor would probably be higher than shown and the slope of the line would tend to remain constant. The data available to the writers are not sufficiently extensive to permit them to be more specific in this regard.

To convert the values shown in Fig. 3 to labor cost, an average hourly wage must be selected. Under the conditions it is necessary to choose some value arbitrarily because it is practically impossible to cover all the local variations in one paper of this type. An average hourly wage of 70 cents has been used herein. Variations of this value are wide in practice.

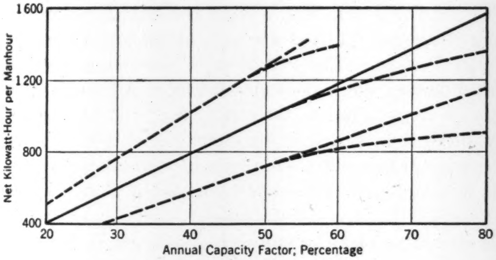

FIG. 3.—NET KILOWATT-HOUR OUTPUT PER MAN-HOUR OF OPERATING LABOR

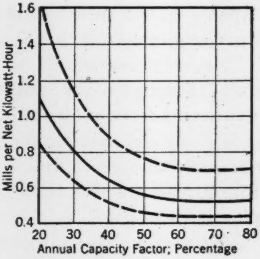

FIG. 4.—MAINTENANCE EXPENSE, LABOR AND MATERIAL

Using 70 cents as the average wage per man-hour for the plants in question, Curves *f* in Fig. 2 are obtained from the values shown by the full line in Fig. 3. These curves are plotted above Curves *e* as a base, so that the ordinates represent the combined costs of fuel and operating labor. The labor costs can be found by difference. As a matter of convenience, the cost of superintendence has been added to the operating labor cost before plotting Curves *f*. The addition is so small as not to make any visible difference in the position of Curves *f*.

Water and Miscellaneous Supplies and Expense.—The next two items of cost, namely, water and miscellaneous supplies and expense, are conveniently grouped together for this kind of generalization. For what may be considered average conditions the grouped cost may be taken at about 0.1 mill per net kw-hr, with a possible variation of ± 50 per cent. However, conditions that are abnormal may cause wider variation as, for example, when water must be purchased from a public supply or when a complicated and costly water treatment is required. The small value adopted as probable cannot be shown clearly in Fig. 2 by drawing an additional curve since this would be only 0.1 mill above Curve *f*. For this reason, the cost of water and miscellaneous supplies has been added to that of maintenance labor and material for plotting purposes.

The task of arriving at reasonable average values for maintenance, labor, and material is difficult. For one thing, standards of maintenance differ greatly from property to property and from region to region. For another, wage scales and costs of materials also vary rather widely. Furthermore, the types of design and construction effect the necessary expenditures; and, by no means least, the type of fuel and certain related factors have a very great influence. Coals with a high sulfur content, ash-fusing at a low temperature and a high water content, all tend to increase maintenance to a significant extent.

For the nominal 225-lb plants, the writers have chosen to use the values given by the full line in Fig. 4. These values are fairly representative of a high grade of maintenance in plants burning reasonably good grades of bituminous coal. The dotted lines indicate probable variations from the values assumed. With very bad fuel or very bad water, the maximum values shown might easily be exceeded. Adding the 0.1 mill for water and miscellaneous supplies and expense to the values shown by the full line in Fig. 4 gives the data for plotting Curves g in Fig. 2. As before, these are plotted above Curves f as a base.

Superintendence, Clerical and Testing.—The last item of operating costs is that designated by superintendence, clerical and testing. Although the service rendered under this item is very valuable, the outlay required to procure it is generally comparatively small. In terms of cost per kilowatt-hour it is generally about 0.1 mill. Obviously, this is too small an increment to plot in Fig. 2, and, for this reason, it was included in the operating labor charge when plotting Curves f.

The total operating cost is then given by the values in Curves g for the two limiting thermal performances assumed. It will be shown subsequently how these performances may be corrected for conditions different from some of those assumed in developing the data thus far presented.

Group 2.—Fixed Charges.—The second large group of cost items is fixed charge expense. A review of the components of this group, as given previously, will show that all are essentially functions of the investment. In fact, each is frequently expressed as a percentage of the investment. It is obvious, therefore, that they can be evaluated immediately if the investment and the various percentages are known.

In connection with investment it should be remembered that this must include, in one way or another, not only the actual plant property, such as land and improvements, buildings, and plant apparatus and equipment, but also those things necessary to convert the plant from a static to an operating entity. In the case of a coal-fired plant, for example, there must be available a sufficient stock of coal to insure power production in the face of an irregular receipt of coal. In the case of certain northern sections of the United States to which such coal is transported *via* the Great Lakes, at least a six-months' supply must be stored when navigation closes. A certain sum of money, therefore, is always tied up in stored coal and represents an investment on which carrying charges must be paid. Again, as an example, a certain amount of working capital must be available in order to pay wages and invoices as they become due. Working capital thus contributes to total investment and, in one way or another, carrying charges must be paid upon it.

The costs resulting from these types of investment are best placed in the third large group ("General Over-Head"), instead of in the second. The carrying charges resulting from the coal storage then go into the general classification of "Stores," and the costs resulting from working capital become part of a larger account of the same character.

Unit investment in power plants, that is, the investment in dollars per kilowatt of capacity, is frequently assumed to be a kind of universally applicable value easily derived. This is very far from the truth. Conditions vary greatly from year to year, from place to place, from method to method adopted or available for construction, and, to a great extent, with the conditions to be met with respect to character of fuel, character of load, provisions for reserve, etc. In years when business is slack, prices and wages tend toward low values and the efficiency of labor tends to increase. A plant built under such conditions should cost appreciably less than one of exactly the same type constructed in the same place under boom conditions. Some districts in which plants are constructed have such combinations of real estate values, building codes, construction practices, and wages that a relatively high cost of plant necessarily results. Some locations require elaborate substructure and expensive canal work, whereas others permit the simplest type of substructure and negligible cost for canals. In some cases, an ample supply of circulating water is available and, in others, expensive provisions for storing and cooling must be made. The result is that one cannot state categorically what a given type of plant should cost or should have cost. It is necessary to study a large number of facts and conditions derived at reasonable figures. How, then, is one to establish a probable investment for the class of plants concerned herein? The unvarnished truth is that one cannot. All one can do is to choose more or less arbitrarily, with full appreciation of the fact that the choice is arbitrary, or consider an entire possible range.

Most of the nominal 225-lb plants were built, or at least partly built, in times of comparatively low prices. Therefore, unless exceptional conditions prevailed in other respects, it would be expected that they should have cost less than they would, had they been built in a period of higher prices. However, in many cases, they have been enlarged during periods of higher prices and, in others, they have been rehabilitated or improved in one way or another, thus increasing the original investment both as to total and as to unit values.

Such data as are available to the writers indicate that the investment in nominal 225-lb plants, as they now exist, will probably fall somewhere between $85 and $110 per kw of capacity under what may be termed average conditions, but that there are exceptional conditions which have produced legitimately both lower and higher values. They have chosen to use $100 for the purposes of calculation, realizing that resultant values for any other condition can be obtained by direct-ratio calculation.

The percentages of this investment, which are to be assumed for each of the items of cost listed under fixed charges, have been the subjects of endless disputes. There are many different theories regarding the manner in which depreciation shall be considered. Political bodies of like character do not agree and different political bodies having jurisdiction, in one way or another, over a given power undertaking, promulgate different rules and use different theories and practices contemporaneously. Regulatory bodies are inclined to consider a high rate of depreciation proper with respect to the past when establishing a rate base, but they accept a low rate of depreciation when establishing a rate for the future on such a rate base. The United States Department of Internal Revenue treats depreciation on a standardized basis and without reference to the practices of State commissions. No agreement exists with respect to the relative values of obsolescence and physical deterioration as aspects of depreciation.

The cost of money is obviously an item that can be determined more or less accurately in any given case either historically or as of a particular time; but there is no reason why it should be the same in any two cases or under any two conditions. One company may be able to, or may have been able to, obtain the required funds at the equivalent of, say, 5.5%, whereas another, just as legitimately, may have paid 7%, or even more.

Property taxes, obviously, vary with the community and the community's practices. In regions of high property values the real estate tax is likely to be high. Personal property taxes are an item in some States and not in others.

Insurance of the types included under fixed charges generally represents a quite insignificant proportion of the total in the case of well built and well maintained properties. However, it also varies widely with the character of the property and the practices of the management.

In view of all these variations it seems best, in the present case, to lump all fixed charges into one percentage value. Such a value appears to vary between slightly less than 10% of the investment as a lower limit, to possibly as much as 14% as a high limit. The writers have chosen to use 12% for the purposes of computation, realizing again that the results can be corrected easily to any other value if it is found necessary.

With a unit investment of $100 and a fixed charge of 12% annually, the fixed charge per unit of output is obtained by dividing $12 by the kilowatt-hours produced annually per kilowatt of capacity. Values obtained in this manner are plotted as Curves h in Fig. 2, using Curves g as a base.

Group 3.—General Over-Head.—Conditions applying to the third classification of general over-head expense must vary widely from case to case. However, as has been indicated herein, this type of expense always exists even if the items to be included may vary.

It is exceedingly difficult to obtain sufficiently comprehensive data to enable one to determine for each of many properties the value of each item lumped under this heading. On the other hand, it is not nearly so difficult to obtain a close approximation to the total of all such items. Such data as are available to the writers indicate that these totals generally equal from 10% to 25% of the total of Group 1 and Group 2 when all items of general over-head character are taken into account. One might be inclined to believe that there would be a marked difference between industrial plants and public utility plants in this respect. The fact appears to be that this is not normally the case because the items in Group 3, which have no meaning in the case of industrial plants, usually represent a very small part of the total. However, the methods of accounting used may, and frequently do, tend to disguise the actual total of the costs in this group.

Practically no data are available that can be used to indicate the relation of general over-head to capacity factor. This may seem strange at first, but inspection of the items making up the general over-head will indicate that, in any given organization, most of them would tend to remain constant over fairly long periods of time even if radical changes in plant output occurred, for example, as the result of a depression or as the result of a business boom. Under such conditions the total at any time would not truly reflect what might be expected if the output remained substantially at the then value. Again, when companies are found which, respectively, operate a plant or plants at radically different capacity factors over long periods of time, the characteristics of the companies and other controlling factors vary so greatly between themselves that any variation of general over-head with capacity factor may well be assumed to be due to causes other than the respective values of the capacity factors.

Faced with such uncertainties the writers have chosen to show the effects of general over-head on total power cost as a rather wide band instead of as a line. The bands shown in Fig. 2, marked *i*, represent what the total power costs would approximate if general over-head amounted to any value between 10% and 25% of the total of Groups 1 and 2 at each capacity factor. Their purpose here is to call attention to the fact that such general over-head must be considered as an item of power cost in a going concern and that it may be expected to be of significant magnitude, rather than to state an exact value.

It will be recalled that the groups of curves in Fig. 2 have been constructed by making certain assumptions and that reference has been made to the possibility of correcting to other assumptions. The first of these corrections is concerned with variation of back pressure and its effect upon performance. Curves *e*, Fig. 2, represent fuel cost at 1-in., Hg, back pressure. For a higher back pressure the cost will be more because the thermal performance will be poorer. For a lower back pressure the cost would tend to decrease more or less, depending upon the design of the turbine and upon the average load carried.

In the case of the older types of turbine, such as would be expected in plants of the kind discussed herein, there would normally be an improvement down to 0.5-in., Hg, back pressure except at the higher loads. At these higher loads the improvement would normally cease at approximately 0.7 to 0.8 in., Hg. It follows that, for low capacity factors which would generally but not always be associated with low average turbine loads, the effect of lowering the back pressure below 1 in. might be expected to be greater than at higher capacity factors.

The differences thus involved, however, are small in comparison with many others that cannot be evaluated and it seems unreasonable to attempt to take them into account in such a general treatment as contained in this paper. Therefore, the writers have included just one curve for back-pressure correction to the performance of a nominal 225-lb plant. This is shown in Fig. 5 (*a*). The part below 1 in. is dotted to indicate the uncertain character of the correction in this region. The correction factors indicated as percentages can be applied directly to increase or decrease the height of Curves *e* in Fig. 2; or, since all curves in Fig. 2 are plotted with the next lower as base, the same percentage of the values on Curves *e* may be added to, or substracted from, the values of Curves *h*.

It seems pertinent to remark that there are few if any cases in the United States in which a normal year's performance would show an average back pressure, weighted for output or otherwise, of less than 1 in., Hg. Therefore, the negative correction is more of academic than of practical interest. This is another justification for not quibbling over the exact shape of the correction factor below 1 in.

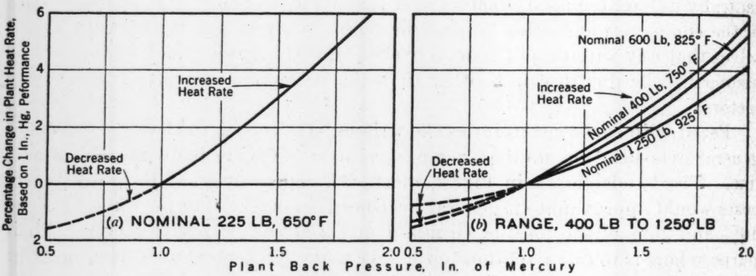

FIG. 5.—AVERAGE CHANGE IN THERMAL PERFORMANCE WITH PLANT BACK PRESSURE BASED AT 1 INCH, HG

Possibly, the next necessary correction is for fuel cost. Curves *e* in Fig. 2 were calculated for a fuel price of 15 cents per million Btu at the boiler, corresponding roughly to about $4 per ton for a good grade of eastern bituminous coal. If any other value such as x cents per million Btu is considered, the values shown by Curves *e* of Fig. 2 must be multiplied by $\frac{x}{15}$. If total power cost is to be shown, it is simpler, of course, to apply the resultant correction to Curves *h* as before.

The next correction factor is for operating labor cost. The values plotted result from assumptions regarding the man-hour output and the average hourly wage. It is obvious that if the man-hour output is assumed at a lower amount, the values indicated by Curves *f* must be increased in inverse ratio, and *vice versa*. It is equally obvious that if a different wage is assumed the values indicated by Curves *f* must be increased in direct proportion and *vice versa*. In making these corrections, as indicated, the presence of 0.1 mill for superintendence and clerical costs in the values shown on Curves *f* is ignored for obvious reasons.

The second group of cost items, fixed charges, is, as stated, based on $100 per kw of capacity and 12 per cent. Alteration in either would produce a corresponding change in the values shown on Curves *h*. The correction would be performed by multiplying the ordinate value between Curves *g* and *h* by the proper ratio.

Reference has been made herein to the effect of oil and gas-firing upon the man-hour output. As a matter of fact, the use of oil or gas instead of solid fuel may have other effects as well, and some of these may result in quite different costs than those obtained for coal-fired equipment. For example, it is obvious that a gas-fired plant receiving its supply through a pipe line owned by others does not have capital tied up in stored coal; it need not have capital tied up in property on which coal is stored; it need not have coal-handling equipment; and it does not have the operating expenses incident to the handling of coal into, and out of, storage and into the plant. These and many other differences may be expected to exist, but no general treatment of the present kind can hope more than to point to that fact. One may state, in general, that, with other conditions equal, the cost of power would be expected to be lower with oil and gas-fired plant than with coal-fired plant; but the significance and importance of the expression, "with other conditions equal," must not be overlooked.

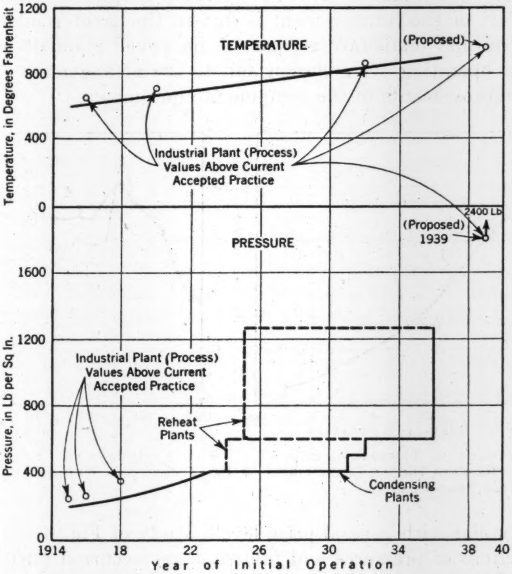

FIG. 6.—INCREASE IN STEAM PLANT TEMPERATURES AND PRESSURES

At this point the writers believe it advisable to introduce a caution. It will have been observed that although the economic performance of any plant at any one time must have a very definite value, great latitude of choice exists as soon as one attempts to generalize. The writers caution against attempts to arrive at probable power cost for a given site or for a general condition by assuming all low or all high limits among those that have been indicated. It seems to be true that in this field, as in others, one seldom, if ever, finds all controlling features most favorable or most unfavorable. Therefore, theoretical power costs, arrived at by making such assumptions, are almost certain to be ridiculous in a practical sense.

Power Costs at Higher Pressures and Temperatures.—Power costs at the higher pressures and temperatures are next considered. These steam conditions have been introduced more or less, successively, as experience, necessity, engineering and design progress, and the development of metallurgy and fabricating processes, respectively, dictated or permitted. The gradual increases of pressure and temperature in the United States are shown in Fig. 6; the year in which each step was taken is indicated. In a general manner, the thermal performance of plants improved during this upward march, is indicated in Fig. 7. Part of the improvement is due to the greater inherent value of higher pressures and temperatures; part to improved plant design, both with respect to the operating cycle chosen and to the arrangement of equipment; and part to improvements in the component equipments.

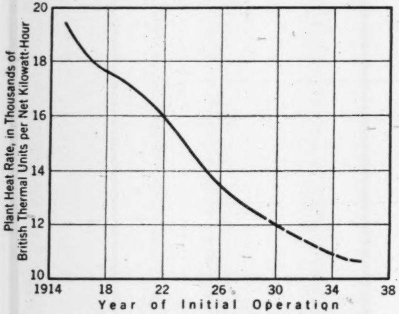

Fig. 7.—Improvement in Thermal Performances (Actual Results for at Least One Year's Performance)

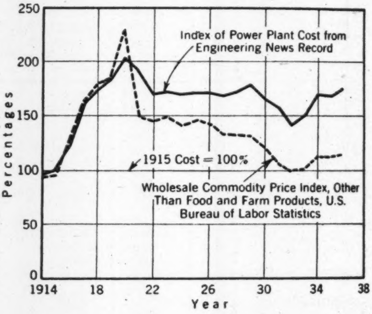

Fig. 8.—Indices of Steam Power Plant Investment and Wholesale Commodity Costs

To one familiar with general price levels, study of Fig. 6 will indicate that the upward climb of pressures and temperatures occurred during a period of relatively high commodity prices, at least up to the end of the last decade. The general effect of changing commodity prices upon the cost of complete power plants is shown very roughly in Fig. 8, for the years 1914 to 1936. Naturally, a combination index such as this is not necessarily accurate with respect to any individual case; it can only reflect conditions in a most generalized or over-all manner. The circumstances in an individual case may legitimately result in wide positive and negative departures from index values.

The phenomena discussed in the immediately preceding paragraphs yield several peculiar results. First, they make it difficult to obtain a true comparison between what may be called basic investment costs of plants built to operate at different pressures and temperatures. Theoretically, one could obtain a perfect index and apply it to the actual known investment costs of different plants built at different times, thus wiping out the effect of varying commodity costs and having the data truly comparable. Practically, this cannot be done because of the impossibility of obtaining so accurate an index for application to isolated cases; because of the wide differences caused by varying local conditions and varying types of design; and because there is no known method of correcting for the extent to which development costs, engineering errors, modified production methods, etc., have been reflected in the actual finished cost in different cases. In another sense, a comparatively small number of radically different units are involved in this case, and statistical methods are not applicable.

Second, these phenomena make it practically impossible to determine the true economic values of different pressure and temperature conditions as separate from the characteristics of any given case. The thermal performances can be found both by computation and by performance statistics from actual plants; but operating expenses and fixed charges are not so readily obtainable in such form as to permit of accurate generalization.

If one tabulates historical costs of plants as they have been built during this period of shifting indices, shifting pressures and temperatures, and shifting design, there appears to have been a gradual increase of cost with increasing pressure and temperature. As nearly as the writers can estimate from the facts, if the nominal 225-lb plant investment were taken at $100 per unit of capacity as was done before, each step in pressure, as herein considered, would probably add about 5% to 7% to the required investment. On the other hand, if one were to consider what can be done in a given location under given conditions to-day, the writers estimate that, starting with the low-pressure investment as indicated previously herein, there would be a slight decrease to a minimum at about 400-lb to 600-lb pressure and then a slight increase to 1 200 lb. The differences involved appear to be small, possibly not greater than 5% to 10% at most. It is quite conceivable that, as experience is gained, as the designs are developed further, as metals are improved, and as development charges are canceled, even this estimate may be changed so as to show a negligible minimum of investment near the middle of this pressure range, or even a gradually falling investment with increase of pressure and temperature to the end.

In view of the kaleidoscopic nature of the variation of investment with pressure and temperature, the writers have thought it best to assume plant investment at $100 per unit of capacity for all cases that follow. This is to be interpreted merely as a ready means of presenting data that can be corrected easily to any set of assumed conditions, rather than as indicating that all these different plants have cost exactly $100 per kw (see, in this connection, the earlier remarks about the use of the same value in connection with nominal 225-lb plants).

The thermal performances obtained from plants operating at 400, 600, and 1 250 lb, respectively, are shown in Fig. 9. As before, the values for each pressure are given as a range to take cognizance of fact. It will be observed that each range overlaps the adjacent range, illustrating once more how difficult it is to apply theoretical values to actual conditions. The wide range of performances for 400-lb plants reflects partly the result of improvement of design and operation in the comparatively long time during which such plants have been built and, to some extent, the variations resulting from different local conditions. The upper limits of the 600 and 1 250-lb ranges are, in a sense, incorrect. They give the performances of plants that are really combinations of two pressures, the higher pressure units having been installed in existing plants operating at a lower pressure and tied in in various ways. They are included because these plants are commonly referred to in terms of the higher pressure, ignoring the existence, and the effect, of the lower pressure.

It will be observed that no performance range is shown for the 800-lb plant although the expectable thermal performance of such a plant as of to-day is indicated by a single line in Fig. 9. The values from which these performance curves for other pressures are developed, are obtained from actual operating plants. It happens that although many 800-lb plants are now (1938) being installed, operating data are not yet available.

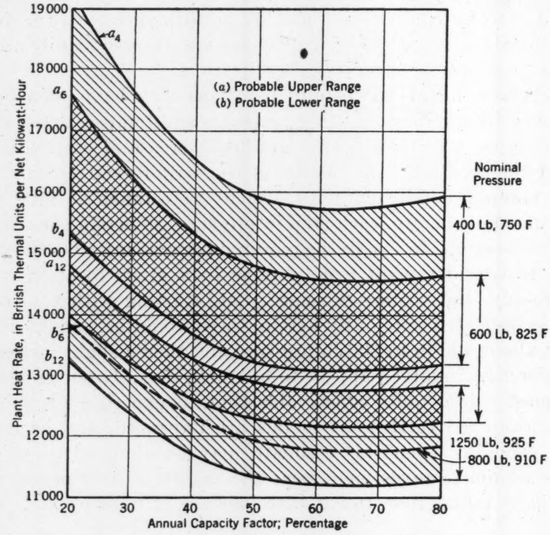

FIG. 9.—THERMAL PERFORMANCE; STEAM PLANT; RANGE 400-POUND TO 1 250-POUND NOMINAL PRESSURE AT 1-INCH HG, BACK PRESSURE

The power-cost data for 400-lb plants are assembled in Fig. 10, in which all curves correspond to those of Fig. 2 and are similarly labeled. (These values, however, are not directly comparable with those shown in similar curves in this paper.) Curves *e* are developed from the upper and lower values shown in Fig. 9, and using a fuel price of 15 cents per million Btu as before. Curves *f* are obtained from the line marked "Nominal 400 lb" of Fig. 11, using a wage rate of 70 cents per hr and adding 0.05 mill for superintendence. Attention is called to the fact that some actual plants are giving a measurably greater output per man-hour, as indicated in Fig. 11, and that if such values were used, the positions of Curves *f* would be lowered. Attention is also called to the fact that no allowance has been made for a probable drooping of the labor performance curve at the upper end, as indicated by dotted lines in Fig. 11.

Curves *g* are obtained from Curve *j*, Fig. 12, with the addition of 0.075 mill for water and miscellaneous supplies. It will be noted that Curve *j* represents a value between the observed limits, Curves *l* and *k*. Data available appeared to indicate its position as approximately correct for a weighted average performance.

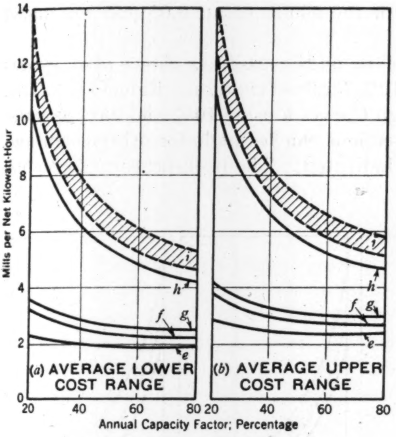

FIG. 10.—AVERAGE UPPER AND LOWER RANGES OF POWER COSTS; NOMINAL 400-LB, 750°F, STEAM PLANT AT 1 IN., HG, BACK PRESSURE

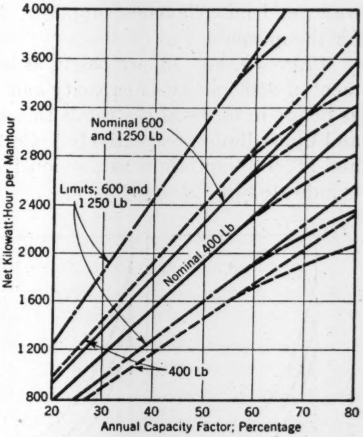

FIG. 11.—NET KILOWATT-HOUR OUTPUT PER MAN-HOUR OF OPERATING LABOR; STEAM PLANT; RANGE, 400 to 1 250-LB NOMINAL PRESSURE

Curves *h*, as already explained, are based on an arbitrary choice of $100 per kw of capacity, and 12% fixed charges. The range, *i*, in Fig. 10, is located as before in terms of percentages of the totals through Curves *h*, the lower limit representing 10%, and the upper, 25 per cent.

Corrections can be made for other conditions and other assumptions as previously noted in connection with the 225-lb plant. The correction to fuel cost for a plant vacuum other than 1-in., Hg, can be made by means of the curve for the 400-lb plant shown in Fig. 5 (*b*). All other corrections are direct ratios as previously indicated.

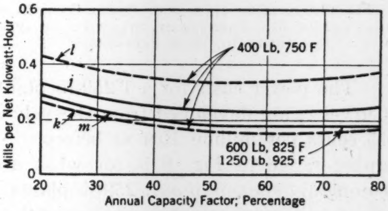

FIG. 12.—MAINTENANCE EXPENSE; LABOR AND MATERIAL; RANGE, 400-LB TO 1 250-LB NOMINAL PRESSURE

The power cost data for a 600-lb plant are given in Fig. 13. Curves *e* are developed from the values shown in Fig. 9 and by using a fuel price of 15 cents per million Btu. Curves *f* are obtained from the line marked "Nominal 600 and 1 250 lb," of Fig. 11, using a wage rate of 70 cents per hr and adding 0.05

mill for superintendence. Curves *g*, Fig. 13, are obtained from Curve *m*, in Fig. 12. This is the first case in which a range has not been shown. The facts are that plants operating at the two pressures indicated are as yet so few and are so comparatively new that the date available could best be shown by a line instead of by an area. As in the previous case, an addition has been made for water and miscellaneous supplies. For the 600-lb plant, 0.05 mill was added for this purpose.

Curves *h*, Fig. 13, are based, as before, on the arbitrary choice of an investment of $100 per kw of capacity and 12% for fixed charges. Range *i* is located as before in terms of the totals through Curves *h* using 10% and 25% as lower and upper limits, respectively. Corrections can be made for other conditions and other assumptions as previously indicated. The back-pressure correction is indicated in Fig. 5 (*b*).

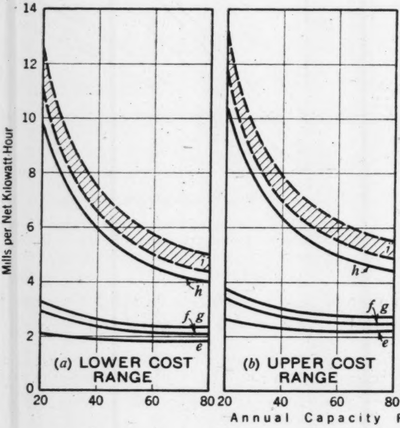

FIG. 13.—AVERAGE RANGES OF POWER COST; NOMINAL 600-LB, 825° FAHRENHEIT, STEAM PLANT AT 1-INCH, HG, BACK PRESSURE

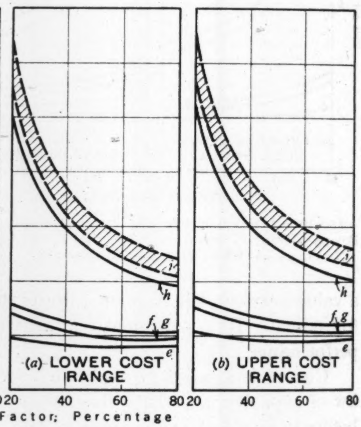

FIG. 14.—AVERAGE RANGES OF POWER COST; NOMINAL 250-LB, 925° FAHRENHEIT, STEAM PLANT AT 1-INCH, HG, BACK PRESSURE

The power costs for a 1 250-lb plant are given in Fig. 14. The fuel costs, Curves *e*, are developed from the values shown in Fig. 9, using a fuel price of 15 cents per million Btu as before. Attention is called to the fact that the upper range in Fig. 9 is for what are really combination plants although commonly spoken of as 1 250-lb plants. It is probable that complete 1 250-lb plants will give a performance near the lower range under what may be called average conditions. Curves *f*, *g*, *h*, and *i*, Fig. 14, are obtained as before and by using the same values as for a 600-lb plant.

It is reasonable to assume that a 800-lb plant would give a thermal performance between those of 600-lb and 1 250-lb plants, respectively, and that all other costs would be the same when computed as has been done herein. It does not seem worth while to complicate a presentation of costs actually achieved by injecting costs based on expected performance.

Inspection of Figs. 2, 10, 13, and 14 will show that the predominating items of cost are fuel and fixed charges. The former will vary directly with the price at which thermal units are available. Strategic location in this respect is frequently possible and, under favorable conditions, from 25% to 50% of the fuel cost item can be eliminated. In fact, there are cases in which fuel is available at a price representing a still greater saving. Many who have concentrated upon the reduction of fuel cost have arrived at the suggestion of a mine-mouth plant which would eliminate all, or practically all, the freight on fuel. This subject has been discussed very extensively in recent years. There are comparatively few locations at or near coal mines where an ample condensing water supply is available and where a sizable load is within a distance permitting it to be reached with transmission lines sufficiently short so that transmission costs do not overbalance the fuel savings. Furthermore, the reliability of over-head transmission is not yet generally regarded as sufficiently high to justify depending entirely upon power transmitted in this manner in the case of loads in which a high degree of continuity of supply is required.

Little more can be written about fixed charges than has been presented already. One may hazard a guess as to unit investment in the future, but it can be little better than a guess. It seems probable that as design experience is gained and as the problems of building and installing high-pressure equipment are solved, high-pressure plants will become relatively cheaper. It also seems probable that, in terms of present-day indices, plants for all the pressures considered will be procurable at costs of less than $100 per kw of capacity under favorable conditions.

It is interesting to speculate upon the future development of steam plants. They are already down to an annual performance of approximately 11 000 Btu per net kw-hr. Power engineers know that this can be bettered by increasing the pressure and by the use of a reheat cycle, or by the increase of both pressure and temperature as metal for superheater tubes and pipe lines becomes available at a sufficiently low price to make such higher temperatures economically feasible. They are already technically possible. The designing engineer for a steam power plant can already envisage the possibility of a performance of 10 000 Btu per net kw-hr, or even a little lower than that.

MERCURY VAPOR-WATER VAPOR PLANT

Several so-called binary vapor combinations have been suggested from time to time as means for reducing the cost of fuel-generated power. Only one of the suggested combinations has thus far shown much promise of economic value. This is the plant using mercury vapor and steam, thermally in series; that is, the heat from the fuel is used primarily to produce mercury vapor and, after the vapor has passed through a turbine, heat remaining in it is used to produce steam for a second turbine.

When the construction of such plant was first undertaken on a semi-commercial scale, its computed thermal performance was so much better than the performance attained with a steam plant that the mercury vapor process held great promise. The very rapid improvement of steam plant, combined with the development of certain practical difficulties in the generation of mercury vapor, has served to retard the wide adoption of this binary process for power production. On the other hand, there has occurred an ever-increasing use of mercury vapor for process purposes.

Now it appears probable that a binary vapor power plant using mercury vapor and steam could be constructed to give a thermal performance of about 9 000 Btu per net kw-hr. Data with respect to the necessary investment are fragmentary and it is not known whether increased fixed charges would, or would not, offset the results of the improved thermal performance. Presumably, the situation will be clarified with the passage of time.

INTERNAL COMBUSTION PLANT

Internal combustion plant is thus far restricted to the use of reciprocating engines and to comparatively small size per prime mover. Large total capacity is obtained by the multiplication of such units. In the United States a few large internal combustion plants have been built which use blast furnace gas for power production in steel plants. With the exception of these rather unique installations, gas-engine and oil-engine plants have been limited to comparatively small total capacity.

Engines using gaseous fuel have not achieved great prominence for the production of electric power, but the Diesel type using liquid fuel has been introduced very rapidly for such purposes in recent years. There are conditions under which it appears to represent the best economic solution of such problems, particularly where comparatively small capacity and high thermal efficiency are desired in combination. Only time can tell whether this is a permanent or a temporary condition. However, there are now indications that point toward the possibility of building comparatively small steam plants of high thermal efficiency, arranged so as to make them competitive with Diesel plants in similar capacities.

The prominence achieved by Diesel engines as prime movers for electricity generation during the past few years justifies consideration of the cost of power obtained from such sources. The writers have arranged cost data for Diesel plant in such ways as to parallel the treatment used in presenting data for steam plant, so that the two shall be, as nearly as possible, directly comparable. Attention, however, is called to the fact that whereas the data for steam were developed for large plants, 150 000 kw, or more, those for Diesel plants are developed for small installations, say, 10 000 kw, and less.

As in the case of steam, all graphs are plotted against annual plant capacity factor. This ratio has been defined herein as the net annual output, in kilowatt-hours, divided by the product of total rated capacity of the plant and the number of hours in the year, namely 8 760. Attention is called to the fact that this factor differs from that commonly used in presenting Diesel plant performance. Direct comparison with the data given herein for steam is permissible; direct comparison with the commonly quoted Diesel plant performance is impossible without preliminary recalculation.

A reasonable fuel cost range is given in Fig. 15. The values indicated by the two curves are based on Diesel engine fuel oil at 5 cents per gal. Corrections can be made by direct ratio for other oil prices. Such prices generally fall between 4 and 6 cents although there are cases in which oil is purchased at prices much lower than 4 cents, and others in which the higher figure is exceeded. It is to be noted that the rather wide range of thermal performance indicated is influenced more by the type of load carried, the character of operation, and the age of the engine, than by the size of the engine. In this statement, age of the engine refers both to the state of the development of the art when it was constructed and to the extent to which it was worn in use.

The values shown in Fig. 15 have been plotted as Curves *e* in Fig. 16, corresponding to the arrangement used in presenting steam data.

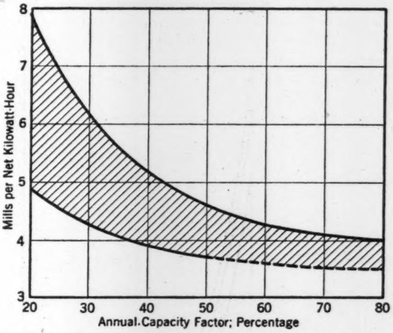

FIG. 15.—FUEL OIL EXPENSE FOR DIESEL PLANTS (OIL AT 5 CENTS PER GALLON)

Curves *f* are derived by using the middle graph of Fig. 17 for output per man-hour and an hourly wage of 70 cents, as before. They represent the cost of operating labor and superintendence plotted above Curves *e* as a base. In this case, operating labor is used partly for maintenance purposes, as is common practice in relatively small plants, so that a part of what is indicated herein as operating labor would be more properly chargeable to maintenance. Plant records do not ordinarily permit this allocation. The upper line of Fig. 17 indicates the output per man-hour that may be expected with a well-designed plant containing a few large modern units. The lower line gives values actually obtained under less favorable conditions. Corrections for different man-hour outputs and for different wage rates can be made easily by ratio computations.

Curves *g*, Fig. 16, plotted above Curves *f*, represent the summary of costs of lubricating oil, miscellaneous supplies, and maintenance to the extent that the latter is not included under operating labor as already explained. The values used for the cost of lubricating oil are taken from the middle curve of Fig. 18. The great range of costs found in practice is indicated by the upper and lower curves of that diagram. It should be noted that all these curves are in terms of oil at 55 cents per gal so that different oil prices are not directly responsible for the wide range that is shown. As a matter of fact Diesel plants are using lubricating oils costing from less than 20 cents to more than 60 cents per gal. There is some indication that the total cost of lubrication is greater with the very cheap oils than it is with the more expensive ones, but this should not be regarded as a proved fact, or as generally applicable. The problem is too complicated and is affected by too many other variables to permit of such simple generalization.

The values used for maintenance cost are taken from the middle lines of Fig. 19. It is possible that, in placing this curve as low as they have, the writers have been unduly influenced by the records of more recently installed plants which may become poorer as these plants age. It seems fairly certain that the line does not belong lower; it may belong as much as 30% higher. The upper range is indicative of what may happen with poorly built, or poorly operated and maintained, equipment.

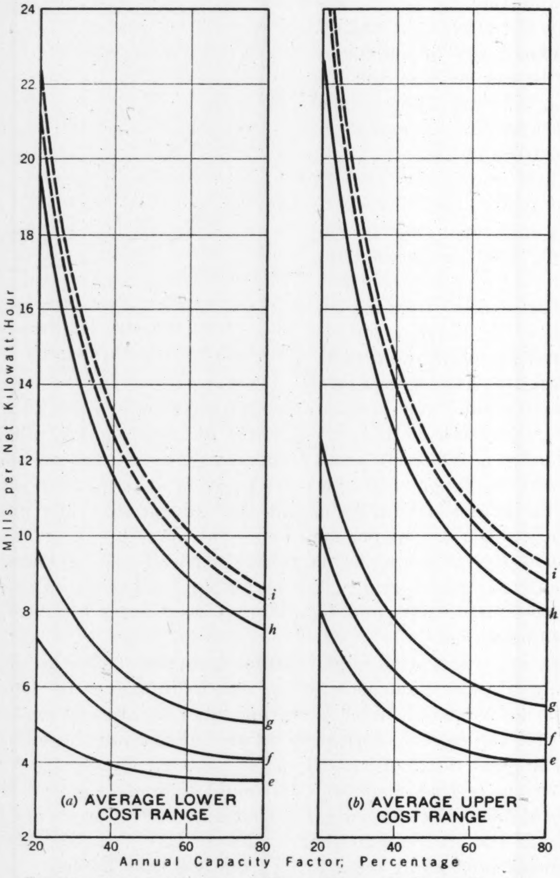

FIG. 16.—AVERAGE RANGES OF POWER COST FOR DIESEL PLANTS

The cost of miscellaneous supplies and expense differs greatly in magnitude, depending upon the local conditions, the grade of "house-keeping," and many other factors. The writers have chosen to use 0.15 mill per net kw-hr at all capacity factors. This appears to be a reasonable average value. Thus Curves *g*, Fig. 16, plotted above Curves *f* as a base, represent the summations of the values given by the middle lines of Figs. 18 and 19 and the constant value, 0.15 mill.

Curves *h*, Fig. 16, plotted above Curves *g* as a base, represent fixed charge expense. At any output this is obviously determined by the investment and the percentage represented by fixed charges. For investment the writers have chosen to use $135 per kw of plant capacity, which they believe represents a fair average value for a complete plant. It is obvious that, with other conditions equal, the unit cost should be greater with a large number of small units as against the same total capacity in a small number of large units. It is also a fact that many local conditions, such as character of soil, availability of water, character of the neighborhood, provision for future enlargement, etc., will all have definite effects upon investment. The choice of $135, therefore, is not to be considered as equivalent to a statement that any and all Diesel plants should be procurable at such a figure but rather that it represents a fair average of both lower and higher values.

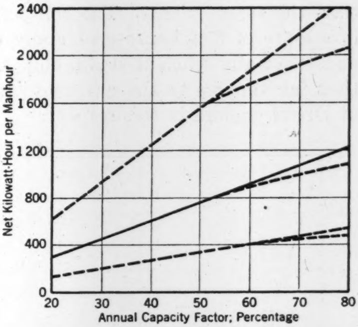

Fig. 17.—Net Kilowatt-Hour Output per Man-Hour of Operating and Superintending Labor for Diesel Plants

The writers have chosen to use 13% for fixed charges as against 12% for steam plant. They believe the higher rate to be justified by the shorter expectable life of Diesel equipment. It is a fact that in some cases such plants have been built recently by municipalities which obtained money at low rates of interest and that in such cases the fixed charges might legitimately be considered as less than 13 per cent. However, it is believed that there are enough operations actually costing more than this percentage to justify its use as a reasonable average value.

Curves *h*, plotted above Curves *g* as a base, then, represent fixed charge expense based on $135 per unit of capacity and 13% as the rate. Obviously, corrections can be made easily for any other value that may be chosen.

The cost of general over-head expense has been shown in Fig. 16 as Range *i*, just as it was in the case of steam plant. The range is plotted on the assumption that this form of expense will vary between 10% and 15% of the totals shown by Curves *h*. The choice of an upper limit lower than that used in the case of steam plant is a recognition of the characteristics of the smaller types of properties that would be using Diesel plant. It is not believed that a value less than 10% can be expected when all items of expense are properly accounted.

At this point the writers call attention to the caution given at the end of the section on nominal 225-lb steam plants. Here, as in the case of steam, one should not assume, without warrant, that all controlling factors will be most favorable or most unfavorable for a given case.

Comparison of expectable cost of power from Diesel plant with corresponding values for modern steam plant, as revealed herein, shows plainly that the latter is capable of producing power more cheaply both with and without the consideration of fixed charges. It should be noted, however, that this result is obtained by comparing values for very large steam plants with those for much smaller plants equipped with Diesel engines. Although not shown by data in this paper, it is true that, in the case of plants of the size represented by existing Diesel installations, the Diesel engine may still give cheaper power than the steam plant. The competitive situation in these sizes is at present in a state of flux because of many current attempts to build cheap, reliable, and thermally efficient steam equipment in the smaller sizes. Progress made thus far appears to the writers to indicate a real challenge to the supremacy of Diesel engines in this respect.

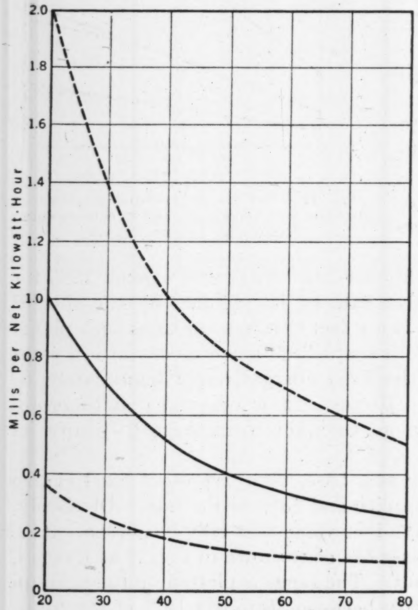

FIG. 18.—LUBRICATING OIL EXPENSE FOR DIESEL PLANTS (OIL AT 55 CENTS PER GALLON)

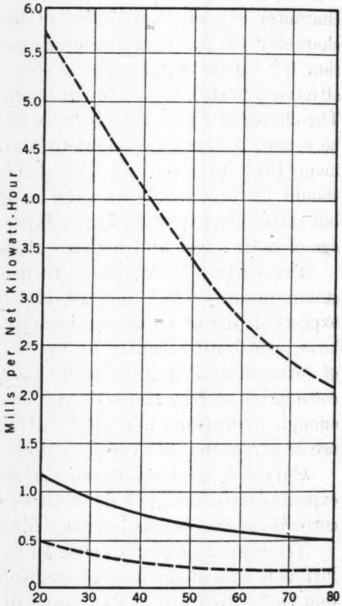

FIG. 19.—MAINTENANCE EXPENSE FOR DIESEL PLANTS

FUTURE POSSIBILITIES

Among other failings, history shows that Man is, in general, a very poor prophet. He has almost always demonstrated inability to imagine the possibility of change because, at the time, he could not envisage the mechanism of it. It is for this reason that the writers hesitate to assume the position of prophet and discuss the future possibilities of fuel-generated power. They recognize too well their own human limitations.

Looking back over the history of fuel-developed power, they recognize the fact that almost every major advance has been made in the face of potential economic loss; that is, the first cost of equipment was generally so high and the supplementary expense involved in making it work was so great, that it required an optimist to incur the very grave possibility of present loss in the hope of future gains. If one attempts now to look into the future with respect to presently visible means of improving thermal efficiencies, one is immediately confronted with the certainty of over-balancing fixed charges. Time after time this condition has caused studious individuals to state that the then present state of development represented the ultimate; and, time after time, they have been proved wrong by subsequent shrinkage of the predicted first cost and a resultant economic gain.

There appears to be no reason for assuming that the same kind of law will not continue to operate. If it does, it is reasonable to assume that with comparatively slight modifications of present methods along lines which can now be foreseen, thermal efficiencies of the order of about 40% may be realized commercially in comparison with the present achievement of about 30% with steam and 35% with Diesel engines. It is difficult to imagine how present types of plants can be perfected to better performance, but this does not mean that it cannot be done.

History also indicates that as Man approaches the ultimate performance with one type of equipment or method, he develops the ability to produce a new, radically different, and better one. It may be that this is indicated in the present instance by the activity in the field of fuel cells; that is, equipments somewhat similar to electric batteries in which fuel is consumed and electric power produced as a result. This development has gone on almost unnoticed by power-plant men until there is now operating in laboratory size a very promising sample of such a cell. No one can say now whether it can be enlarged sufficiently and commercialized, but careful investigation appears to indicate great probability that it may be. Many difficulties can be foreseen, but none of them appears to be of insurmountable character.

The promise is for thermal efficiencies of the order of double or more than double those presently attainable, and with a unit investment not greater than that now required, possibly even less.

Need one go further with respect to future possibilities in this line? It would seem that the chances for continued reduction of total power cost at the fuel-burning generating plant are indeed very large.

HYDRO-GENERATED ENERGY

By H. K. Barrows,[4] M. Am. Soc. C. E.

Synopsis

This paper presents an analysis of the plant characteristics and elements of cost of hydro-generated energy based upon an investigation and study of data regarding fifty-seven hydro-plants scattered throughout the United States. Attention is given particularly to hydro plants in power systems where hydro and steam power are complementary in use, and a method of evaluating such hydro-power costs is suggested, which takes into account both energy and capacity values.

Some of the larger Federal hydro-projects are also discussed and compared in cost with those of private utility companies and a brief survey is made of water-power resources not as yet developed.

Essential Features and Types of Development

The general requirement of a hydro-electric plant is a flow of water, as uniform as may be, held back usually by a dam so that it may create a head on hydraulic turbines, and by passing through them under this head or pressure, create electric energy by means of the generator, now usually direct-connected with the turbine.[5]

A hydro-development, therefore, requires a dam in most cases. Where the head utilized is only that created by the dam in what is called a "concentrated fall development" the power-house is situated just below the dam, the water reaching the turbines through a flume or penstock and again entering the river after passing through the turbines. In some cases, water from the turbines passes back to the river by a tail-race channel, which often is of considerable length.

Frequently, it is advantageous to direct the water from the dam for some distance down river by a waterway, thus obtaining additional head by what may be termed an "extended fall" development. Depending on the quantity of river flow, as well as the topography near the river and the head developed, the waterway may be an open canal, a closed pipe or penstock, or a combination of both. Wood-stave, steel, and reinforced concrete pipes or penstocks are all in use for such waterways. Occasionally, a tunnel is used for the waterway, where conditions make it economical.

The power-house is commonly rectangular in shape, with vertical turbine-generator units in a line along the length of the building and spaced to permit, in the concrete substructure, the necessary width of approach flumes to the turbines as well as draft-tubes and tail-race channels. The type of flume and turbine setting for reaction wheels depends chiefly upon the head developed, as follows:

---

[4] Prof. of Hydr. Eng., Mass. Inst. Tech.; and Cons. Engr., Boston, Mass.

[5] "Water Power Engineering," by H. K. Barrows, 1934.

Head, in feet (approximate)	Type of approach flume
20 to 30, or less	Open pit
20 to 50	Concrete scroll
30 to 350	Plate-steel scroll
350, or more	Cast-steel scroll

The modern hydraulic turbine unit is commonly of the vertical, single-runner type, with a vertical generator set above the turbine and direct-connected with it. Proper control of speed is obtained by the hydraulic governor and pressure regulation (in the case of other than low heads), by a surge tank, usually now of the differential type, placed in the penstock as near to the turbines as practicable.

For higher heads, particularly 1 000 ft, or more (but depending also upon capacity), impulse wheels are used, in which the water passes through a nozzle to the buckets of the wheel. These wheels are usually set on a horizontal shaft and may be single overhung or (for larger units) double overhung, with reference to the generator supports. The general arrangement of such installations is similar to that of reaction turbines, except that no draft-tube is used, the water from the wheel entering a tail-race channel.

The power-house superstructure is usually of brick or reinforced concrete and contains the generators, switching, and other electrical equipment. It is now common practice to install the transformers, lightning arresters, and high-tension electrical equipment in an outdoor yard. In this paper, costs at the switchboard are considered and no transmission costs are included.

Following is an outline of the essential features of the hydro-electric plant as considered in this paper, and common types of construction:

1.—Dam:
  - (*a*) Non-Overfall Section:
    - Solid concrete;
    - Hollow concrete;
    - Earth (with or without core);
    - Timber.
  - (*b*) Spillway:
    - Solid concrete;
    - Hollow concrete;
    - Tunnel type;
    - Lateral channel type.

2.—Waterway (Including Tail-Race):
  - (*a*) Canal or Open Channel:
    - Lined;
    - Unlined.
  - (*b*) Penstock or Pipe:
    - Wood stave;
    - Steel;
    - Concrete.

- (*c*) Combinations of Canal and Penstock.
- (*d*) Flume:
  - Wood;
  - Concrete;
  - Steel.
- (*e*) Tunnel.
- (*f*) Tail-Race:
  - Open-channel (protecting wall or embankment).
- (*g*) Surge Tank:
  - Simple;
  - Differential.

3.—Power House and Equipment:
- (*a*) Building:
  - Substructure (concrete).
  - Superstructure:
    - Brick;
    - Concrete.
- (*b*) Equipment:
  - Hydraulic:
    - Turbines and governors;
    - Relief valves.
  - Electrical:
    - Generators;
    - Switching equipment;
    - Conduits.
  - Miscellaneous:
    - Crane;
    - Station service.

4.—Reservoir Requirements; Changes in:
- (*a*) Highways;
- (*b*) Railroads;
- (*c*) Manufacturing plants;
- (*d*) Other structures;
- (*e*) Clearing.

5.—Land and Water Rights:
- (*a*) Real Estate:
  - Land;
  - Buildings.
- (*b*) Water Rights:
  - Flowage;
  - Power and riparian rights.

ISOLATED AND SYSTEM PLANTS

In this paper, attention will be given chiefly to hydro-plants in a power system in which, usually, other hydro-electric as well as steam electric plants are included. This is of importance as affecting requirements for spare units as well as auxiliary power that may be needed in the case of isolated hydro-plants in which dependence upon continuous service is essential and for which assistance from other plants in a system is not available.

A hydro-plant in a power system also makes possible a better and more economical use of hydro-electric power than can be the case with an isolated hydro-plant.

PLANT CAPACITY WITH REFERENCE TO FLOW

Based upon average yearly flow-duration curves constructed with the lower flows toward 100% of the time, hydro-plant capacities, as constructed, generally vary between a flow available from about 60% of the time to one available only a small part of the time. Of course, this reflects, to a large extent, the capacity or use-factor requirements.

TABLE 1.—INSTALLED WHEEL CAPACITIES AT HYDRO-ELECTRIC PLANTS

Plant	Drainage Area, in Square Miles		Head, in Feet		Wheel Capacity			
					Discharge, in Cubic Feet per Second per Square Mile		Percentage of the Time That Discharge Is Available

* Plants 2, 3, 4, and 5. † 1938.

Table 1 contains some actual wheel capacities at different plants expressed in both cubic feet per second per square mile of flow and as the percentage of time that flow is available in the average year.

As will be noted from Table 1, system hydro-plants, when not especially designed for day use, generally show a wheel capacity corresponding to the flow available about 20% to 30% of the time. The day or peak-load plants (Fifteen Mile Falls, Harriman, Safe Harbor, and Tallulah Falls) usually have wheel capacities of about 5% or less of the time flow.

DEFINITIONS

Load Factor.—The ratio of the average load over some period of time, as a day, week, month, or year, to the maximum or peak load during that time measured during a short time, as a few minutes, is termed the "load factor." Plant load factor applies to any particular hydro-plant under consideration.

System load factor applies to the power system in which the hydro-plant is an integral part.

Capacity or Use Factor.—The ratio of the average load of the hydro-electric plant over some period of time to the plant capacity, is its capacity factor, or use factor. Note that with maximum load at plant capacity, the plant load factor is the same as the plant capacity factor.

Utilization Factor.—The ratio of the average hydro-plant output over some period of time to the power available in the stream with the plant wheel efficiency and head, and as limited by plant capacity, is known as the "utilization factor." Stated more simply, this is the ratio of power output to power available.

The foregoing factors for a hydro-electric plant in a power system vary commonly about as follows (expressed as percentages):

Factors	Comparison
Yearly load	From a small percentage (often less than 10% with peak-load plants) to about 70% or more under very favorable operating conditions
Yearly capacity	From about 30 to 60%
Yearly utilization	From about 40 to 70%

Primary, or Firm Power.—Referring to hydro-power, "primary power," or "firm power" is the dependable power, or that which is continuously available at the plant under the conditions of use. It is defined by the extreme low-water flow, although sometimes it is taken as the flow available 95% of the time where low flows of record are affected by pondage, particularly at week ends.

Primary or Firm Capacity.—Referring to the use of hydro-electric power in system loads, "primary capacity" or "firm capacity" is the part of the total installed capacity that can perform the same function on that part of the load curve to which it is assigned as could be performed by an alternative steam plant. In this case the primary capacity of a hydro-plant would be based on the power available at low-water flow (or sometimes due to back-water conditions), but concentrating the use of this flow at the time of system peak by means of pondage, to replace steam capacity as far as possible.

ELEMENTS OF COST OF HYDRO-ELECTRIC GENERATED ENERGY

The dominating element of cost is that of the fixed charges upon cost of plant. These charges will ordinarily include:

Items	Percentage
Interest	5 to 7
Depreciation	1 to 2
Taxes and insurance	1 to 2
Total	7 to 11

A fair allowance is 10% under usual conditions. It is to be noted that a hydro-plant often includes a large proportion of essentially permanent construction, such as dams of earth or concrete, tending to lessen the necessary physical depreciation allowance. Moreover, hydro-plants are usually located in the less settled parts of the country, so that the item of taxes is less than that for steam plants in urban regions. Other minor items of cost of hydro-electric energy are attendance and ordinary maintenance items. These costs will not usually total more than 0.1 ct per kw-hr, even with relatively small plants, and for larger plants the total is usually from 0.02 ct to 0.04 ct per kw-hr. Hence, the cost of hydro-electric energy is essentially that of fixed charges.

Evidently, the cost per kilowatt-hour of hydro-electric energy will vary inversely with the plant capacity factor. Thus, a plant of 10 000 kw, costing $150 per kw, or $1 500 000, would have fixed charges of $150 000 per yr. With a capacity factor of 60% the plant would produce 6 000 kw as an annual average load, or about 52 million kw-hr per yr, costing 0.29 ct per kw-hr.

With a capacity factor of 30% there would be a yearly average load of 3 000 kw, or 26 million kw-hr, costing 0.58 ct per kw-hr, which is twice the cost for a 60% capacity factor.

Curves by means of which fixed charges for hydro-plants (in cents per kilowatt-hour) may be obtained for different plant costs per kilowatt and different plant capacity factors may be constructed.[6] From a curve based upon 10% fixed charges, the cost per kilowatt-hour for other percentages of fixed charges, can readily be obtained by proportion. As previously noted, fixed charges are essentially the cost of hydro-electric energy.

HYDRO-GENERATED ENERGY IN A POWER SYSTEM

Two aspects of hydro-electric power as used in a power system are of importance:

(1) At the wetter seasons of the year (particularly in the spring, when water is available up to and beyond plant capacity) the hydro-plant may be used to carry some, or all, of the base load part of the demand, thus saving principally in fuel cost of steam plants; and

(2) In the medium and low-water seasons the hydro-plant may be used to carry peaks, or the upper part of the load curve, thus saving in respect to steam capacity. Aspect (2) is of much importance, as in the upper part of the usual load curve the proportion of energy to that of the daily total is relatively small for a considerable range of required capacity. In other words, the peaks are of relatively short duration, with the result that a hydro-electric plant carrying, say, the upper 10% of daily energy will include approximately 20% to 40% of peak capacity, depending on the system load curve and load factor.

It should also be noted that the extent to which the system peak is already taken by hydro is of importance in the consideration of additional hydro-plants. The first hydro-plant in the system occupies the favored position at the top of the curve, hence a second plant, as it must take a lower and less advantageous position on the load curve, is usually more difficult to justify.

---

[6] For an example of this style of plotting, see *Electrical World*, August 14, 1937, p. 100 (570).

Existing conditions are thus of importance in determining the economic justification of new hydro-plants.

The relations of the percentage of daily energy carried by water power and the percentage of peak load carried by the hydro-electric plant are shown in Fig. 20 for system load factors of 0.4, 0.5, 0.6, and 0.7. Each of the curves shown therein is the result of a study of groups of load curves through the given range of load factors and will serve for use in preliminary estimates and studies.

Assuming that a hydro-electric plant supplies 10% of the daily energy for a system with an average daily load of 300 000 kw, or 7.2 million kw-hr daily, the hydro-plant carries 720 000 kw-hr daily, or an average load of 30 000 kw, which latter value might represent the primary 24-hr flow at the site. Referring to Fig. 20, the hydro-plant could carry peak loads, as shown in Column (4), Table 2, for different system load factors. The assumed conditions are shown graphically in Fig. 21.

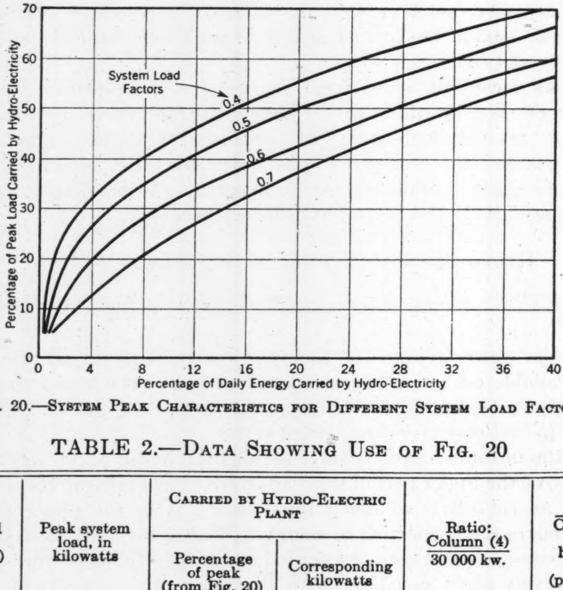

FIG. 20.—SYSTEM PEAK CHARACTERISTICS FOR DIFFERENT SYSTEM LOAD FACTORS

TABLE 2.—DATA SHOWING USE OF FIG. 20

System load factor (percentages)	Peak system load, in kilowatts	CARRIED BY HYDRO-ELECTRIC PLANT		Ratio: $\frac{\text{Column (4)}}{30\,000\text{ kw.}}$	$\frac{1}{\text{Column (5)}}$, or hydro-load factors (percentages)
		Percentage of peak (from Fig. 20)	Corresponding kilowatts		
(1)	(2)	(3)	(4)	(5)	(6)
40	750 000	43.5	327 000	10.9	9.2
50	600 000	38.0	228 000	7.6	13.1
60	500 000	31.5	157 000	5.2	19.2
70	430 000	24.	103 000	3.4	29.5

In Column (5), Table 2, is given the ratio of kilowatts carried by the hydro-plant at the time of system peak load to the hydro-plant average 24-hr load. This shows that, depending on the system load factor, if used at the time of system peak load the plant can supply peak capacity of 3.4 to 10.9 times the amount available on a 24-hr steady use basis. Plant load factors will be the reciprocal of values in Column (5) × 100 and, as will be noted, will vary from approximately 9 to 30 per cent.

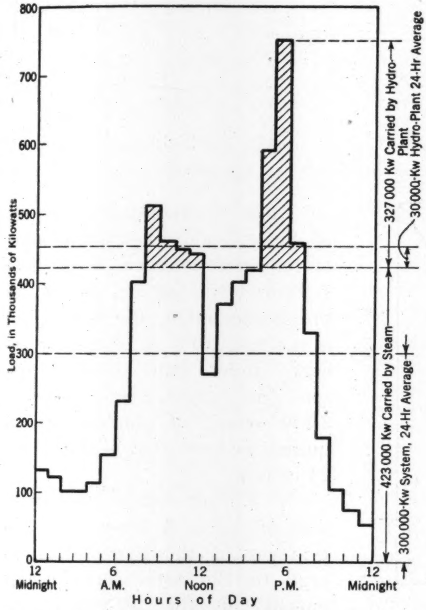

FIG. 21.—USE OF WATER POWER FOR PEAK CAPACITY; SYSTEM LOAD FACTOR, 40 PER CENT

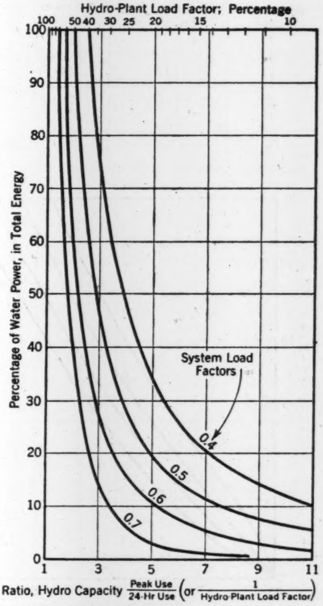

FIG. 22.—USE OF WATER POWER ON SYSTEM PEAKS

Fig. 22 is obtained by computations similar to those for Columns (5) and (6), of Table 2, for various values of percentages of water power in total daily energy (based upon Fig. 20), and shows directly, for different system load factors, the relation of peak hydro-electric capacity (when used at the time of system peak) as compared with its 24-hr use, and by auxiliary scale at the top, the corresponding hydro-load factors.

PONDAGE

Pondage is necessary at the hydro-plant, of course, in order to make possible the use of hydro-electric power at the time of the system peak. The number of hours per day during which water is being used and, by another scale, the hours of collection of water, or pondage, are given approximately by Fig. 23, for different percentages of system peak carried by the hydro-electric plant.

Referring to the previous example and assuming that the 30 000 kw of 24-hr primary hydro-electric power is developed under a head of 200 ft, requiring about 2 250 cu ft per sec with 100% utilization, the data in Table 3 are obtained.

TABLE 3.—DATA FOR THE USE OF FIG. 23

System load factor (percentages) (1)	Percentage of peak carried by hydro-plant (Column (3) in Table 2) (2)	Hours of use (Fig. 23) (3)	Hours of pondage 24 − Column (3) (4)	PONDAGE REQUIRED		Portion of 24-hour flow ponded $\left(\frac{\text{Column (4)}}{24}\right)$ (7)
				Cubic feet per second-hours (Column (4) ×2 250) (5)	Acre-feet (Column (5) $\times \frac{3\,600}{43\,560}$) (6)	
40	43.5	7.0	17.0	38 000	3 140	0.70
50	38.0	7.5	16.5	37 000	3 060	0.69
60	31.5	8.0	16.0	36 000	2 970	0.67
70	24.0	8.0	16.0	36 000	2 970	0.67

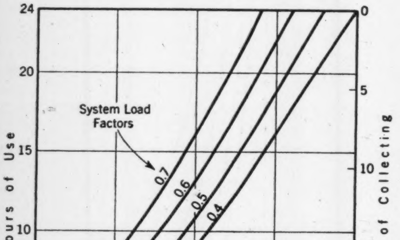

FIG. 23.—PONDAGE; TIME OF USE AND OF COLLECTION FOR DIFFERENT SYSTEM LOAD FACTORS; WATER POWER USED ON SYSTEM PEAK

Table 3 demonstrates the use of Fig. 23 and the computation of required pondage for different system load factors, where, as previously noted, the hydro-plant is carrying 10% of the daily energy, under four different system load factors. From 2 970 to 3 140 acre-ft of pondage are required, or from 0.67 to 0.70 of the 24-hr flow.

A further study similar to that of Table 3 for various percentages of the hydro-plant energy to the total daily energy output of the system shows (with only minor variation with system load factor) approximate pondage requirements as follows:

Hydro-electric energy in percentage of daily energy	Pondage requirements (ratio to 24-hr flow)	Hydro-electric energy in percentage of daily energy	Pondage requirements (ratio to 24-hr flow)
2	0.85	8	0.71
4	0.78	10	0.68
6	0.74	15	0.61

Note that with less than 100% utilization of river flow, less pondage is required; but operation of the hydro-plant for peak loads will usually be with fairly complete utilization.

Although there is some approximation in the foregoing methods the general results are sufficiently accurate to indicate general pondage requirements and show that pondage, to the extent of about 60 to 85% of the 24-hr flow, is required for its peak load hydro-electric use, depending on its percentage of the total daily energy.

FIRM CAPACITY OF HYDRO-PLANT

As previously noted, the usual hydro-plant capacity in a power system corresponds to about the flow available 20% to 30% of the time. Peak or day-load plants will be at about the 5% flow or a somewhat lesser percentage (higher capacity) in some cases. The primary 24-hr flow may be taken at about the 95% flow.

The general form of the average flow-duration curve in regions where water power is in general use is shown approximately by the following two equations:

East and South:

$$\log Q = 2.45 - 0.011\, T \quad \text{(1)}$$

West:

$$\log Q = 2.52 - 0.013\, T \quad \text{(2)}$$

in which Q is the discharge expressed as a percentage of the mean yearly discharge, and T is percentage of time. Table 4 is based upon Equations (1) and (2). It will be noted that ordinary hydro-wheel capacities will be from about six to eight times the primary 24-hr power, and peak or day-load hydro-plants ten or fifteen times the primary 24-hr power.

TABLE 4.—FLOW RELATIONS

Percentage of time that flow is available	FLOW AS A PERCENTAGE OF AVERAGE YEARLY FLOW		RATIOS TO FLOW AVAILABLE 95% OF TIME	
	East and South	West	East and South	West
5	250	285	10.	15.0
20	170	182	6.8	9.6
30	132	135	5.3	7.1
95	25	19	1.0	1.0

It will be seen that, in many cases, depending upon the extent of hydro-power use and system load factor, the entire hydro-electric capacity may be firm, or largely so, when used on the system peak. Thus, in the example previously given (see Table 2), in which the primary 24-hr power was 30 000 kw, the wheel capacity would be ordinarily about 8 × 30 000 = 240 000 kw; or, if a peak or day-load plant is considered, 15 × 30 000 = 450 000 kw. The proportion of plant capacity that would be firm for different system load factors would then be as given in Table 5.

TABLE 5.—FIRM PLANT CAPACITIES

System load factor (percentage)	Carried by hydro-electric plant (Column (4), Table 2), in kilowatts	PROPORTION OF PLANT CAPACITY THAT IS FIRM	
		Plant capacity, 240 000 kilowatts	Plant capacity, 450 000 kilowatts
40	327 000	All	0.73
50	228 000	0.95	0.51
60	157 000	0.65	0.35
70	103 000	0.43	0.23

PEAK CAPACITY VALUE OF HYDRO-PLANT

The essential or important result of using water power on the peak of the system load is to save steam capacity. The cost of a steam plant is approximately \$100 per kw.[7] In comparing with water power, the ratio of fixed charges (10% for water power and 12.5% for steam power) would require a factor of 1.25, making the comparative cost of the steam plant, \$125 per kw. This may be regarded as a credit item on the cost of hydro-plant when the latter can be used for system peak loads.

Thus, to illustrate this suggested method of procedure, assuming that a hydro-plant in use for saving in system peak capacity costs \$200 per kw and that three-fourths of its capacity is firm, the credit on account of capacity saving would be, say, $\frac{3}{4} \times \$125 = \$94$ per kw, leaving a net cost of \$106 per kw for the hydro-plant. The yearly capacity factor for such a plant might be 0.5 (if used for base loads in the wetter seasons) and its fixed charges, 0.24 ct per kw-hr. With allowance for operating and maintenance costs, this would be about 0.27 ct per kw-hr as the total cost of hydro-electric energy.

This cost of hydro-electric energy would compete with fuel and attendance costs of steam power. With coal at \$3.00 per net ton and 1.5 lb per kw-hr, fuel would cost 0.225 ct per kw-hr, and attendance about 0.10 ct, or a total of 0.32 ct per kw-hr—showing some margin in favor of the hydro-plant with conditions as assumed.

This method of crediting or allowing for capacity value of a hydro-plant for peak use in a load system and regarding the hydro-electric energy output as affecting fuel saving and attendance charges enables the consideration of the total hydro-electric output and renders unnecessary the segregation of that part commonly called primary. In an actual case the steam capacity saving would be determined by taking into account the primary 24-hr power, pondage, actual wheel capacity, and the actual system load curve. The foregoing method is only approximate and is used merely for illustrative purposes. An illustrative example using actual data for the Conowingo plant is given subsequently herein.

COST OF HYDRO-ELECTRIC PLANTS

Supporting Data.—Cost data for hydro-electric plants have been obtained as a basis for study in this paper from two general sources:

(1) From the files and annual reports of the Federal Power Commission[8] at Washington, D. C., plant characteristics and data of cost for thirty-four hydro-plants in different sections of the United States and especially in the West. These factors are given in detail in Table 6 (see project numbers in Column (2)); and,

(2) By correspondence with engineers and other officials of public utility companies, as well as from personal files of the writer, giving similar data of characteristics and cost for twenty-three hydro-plants, fairly well distributed generally. These data are also given in detail in Table 6 and are

distinguishable from Source (1) in that they do not have project numbers (see Column (2)).

Most of the items in Table 6 need no explanation. As applied to Federal projects, head, in feet (Column (8)), is the gross or static head, as the actual working heads were not available. For non-Federal projects, the head is given as the working, or net, head, except as otherwise stated. Annual output (Table 6, Column (10)) is given as an average value for such years as are available. However, where load is increasing the latest year of record is used. The values in Column (13), the ratio of pondage to wheel capacity, are obtained by dividing the pondage capacity, in second-feet-days, by the flow at wheel capacity, in second-feet.

Costs (Columns (14) to (19), Table 6) are as recorded, except as condensed into the break-down used in Table 6. Undistributed over-head costs, where they occur, have been pro-rated. Under the heading, "Cost, in Dollars per Kilowatt of Capacity" (Columns (25) to (36), Table 6) certain projects include only a small item for the cost of the dam where power is developed at a navigation dam.

Under "Annual Cost of Power" (Column (37)), note that fixed charges are taken at 10 per cent. In certain projects an item of production rental is included to allow for fees paid yearly to the Federal Power Commission. The cost per kilowatt-hour (Column (41)) is the cost of total power output, including both primary and secondary power.

Range of Conditions.—That the information in Table 6 is representative is indicated by the range of conditions that characterize the 57 plants included. Geographically, 15 are in the East, 15 are in the Southern and Central States, and the remainder (27) are in the West. In point of age, the dates of construction, or of beginning operations, are as follows: 1908 (1); 1920 (1); 1921 (3); 1922 (1); 1923 (4); 1924 (6); 1925 (4); 1926 (7); 1927 (11); 1928 (6); 1930 (4); 1931 (4); 1932 (2); 1933 (1); and 1937 (2).

Other characteristics are:

Description	Range
Capacity, in kilowatts	400 to 252 000
Head, in feet	13 to 2 561
Yearly output, in million kilowatt-hours	1.5 to 1 300
Cost of plant, in thousands of dollars	91 to 50 450
Cost, in dollars per kilowatt of capacity[9]	95 to 479
Cost, in cents per kilowatt-hour[10]	0.16 to 3.74
Yearly capacity factor	0.10 to 0.94

The fifty-seven plants have a total capacity of about 2 190 000 kw; they cost about $384 000 000, or an average of about $175 per kw. Their total yearly output is about 9.5 billion kw-hr (or about one-fourth the total public utility water power output of the United States for 1936) at an average cost of 0.44 ct per kw-hr.

---

[9] Uses Government dam.

[10] Plant built in 1908.

Effect of Head and Capacity upon Cost.—The cost per kilowatt of capacity is plotted against head in Fig. 24. The size of the plant is approximated by circles of varying diameter, the numbers referring to the plant number in Table 6. In general, the unit cost decreases as the head increases and the larger plants generally show lower unit costs. By grouping plants according to head, as in Table 7, general tendencies are revealed more clearly, as shown by the dotted line drawn through the group points in Fig. 24.

TABLE 7.—ELEMENTS OF PLANT COST WITH REFERENCE TO HEAD (Fifty Plants)

Item	AVERAGE HEAD AND RANGE, IN FEET, AND NUMBER OF PLANTS							
	37 (13–64) 14 Plants		209 (78–370) 24 Plants		568 (410–860) 5 Plants		1 550 (1 050–2 561) 7 Plants

Four plants in Table 6 are omitted from Table 7, because use is made of a Government dam, and three because the head is not known. Table 7 also shows group costs per horse-power and the percentage of the following five items of cost breakdown:

(1) The cost of the dam varies from \$123 per kw for the low head groups to \$13 for very high heads and is from about 40% to 10% of the total cost;

(2) The cost of the waterway varies from \$13 per kw for low heads to \$85 per kw for very high heads and is from about 5% to 60% of the total cost (the cost of the dam plus the waterway remains more nearly constant, varying from \$136 per kw for low heads to \$98 per kw for very high heads, and is from about 50% to 70% of the total cost);

(3) The cost of the power-house and equipment varies from about \$100 to \$35 per kw, and is about 30% of the total cost;

(4) In general, highways, railroads, etc., are relatively unimportant; and,

(5) Land and water rights vary from about \$40 to \$5 per kw, and are about 15% or 20% for the two lower groups, lessening to about 5% at very high heads. In the case of some of the plants in Table 7, the item of water rights is (in part, anyway) covered by yearly rental charges.

It must be kept in mind that the foregoing items are average costs based upon groups of plants as noted. Individual plants will vary greatly from the values given. The averages, however, show the trend of unit cost of different parts of the hydro-plant as the head varies.

COST OF WATER-POWER OUTPUT

Effect of Head, Capacity, and Capacity Factor upon Cost.—In Fig. 25(*a*) hydro cost per kilowatt-hour of output is plotted against head, these data being taken from Table 6. Capacity is shown approximately by the size of circles and capacity factor by radial lines in the circles as noted. The numerals refer to plant numbers in Table 6.

Although, in general, the cost per kilowatt-hour tends to lessen as head increases and to lessen with the size of the plant, the effect of capacity factor is more predominant. Note, for illustration, the group of points between 300-ft and 400-ft head, in Fig. 25(*a*). The upper points have low capacity factors and the lower points, high capacity factors. If all are reduced to, say, a 0.50 capacity factor, the points will be relatively near together. This adjustment has been made for all the points of Fig. 25(*a*) and replotted in Fig. 25(*b*) on the basis of a 0.50 capacity factor for all plants and, as will be noted, the major variations in the plot of Fig. 25(*a*) are thus largely eliminated.

The effect of capacity factor upon cost of output is also shown in Fig. 26, where cost per kilowatt-hour of output is plotted against capacity factor, irrespective of head. This also reveals more clearly the smaller cost of output from the larger plants.

Referring again to Fig. 25(*a*), the range in actual costs per kilowatt-hour is seen to vary as Table 8(*a*). From Fig. 25(*b*) the range, adjusted to a constant capacity factor of 0.50, is as shown in Table 8(*b*). The latter data reveal more clearly the range in costs due to variation in what may be called "site cost factor," or the natural conditions at sites tending toward a greater or less construction cost. The capacity, or use factor, refers to the method of plant operation and, obviously, the differences in cost in Table 8(*a*) and Table 8(*b*) are due solely to different assumed methods of operation, and consequent difference in capacity factors.

TABLE 8.—COSTS OF WATER-POWER OUTPUT, IN CENTS PER KILOWATT-HOUR

Head, in feet	(*a*) RANGE OF ACTUAL COSTS		(*b*) RANGE OF COSTS, ADJUSTED TO A CONSTANT CAPACITY FACTOR OF 0.50	
	From:	To:	From:	To:
Less than 100	0.3	3.7	0.2	1.2
100 to 500	0.16	2.2	0.3	1.1
More than 500	0.35	1.3	0.25	0.55

PRIMARY COST OF WATER POWER

Frequently, plant cost per kilowatt, as well as cost per kilowatt-hour of hydro-electric energy, is based upon the power corresponding to the 24-hr primary flow. This is logical in the case of an isolated plant, but misleading

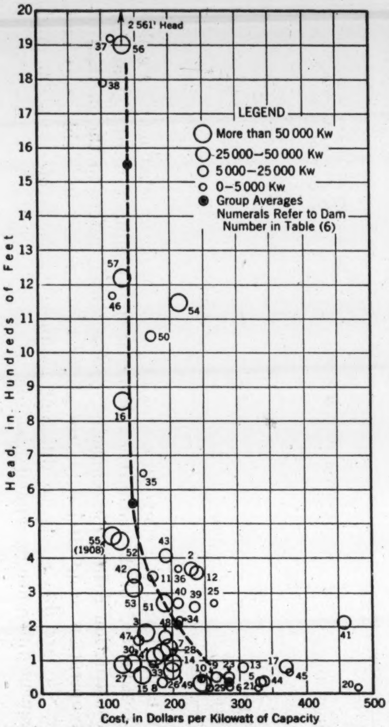

FIG. 24.—PLANT COST OF WATER POWER AS AFFECTED BY HEAD AND CAPACITY

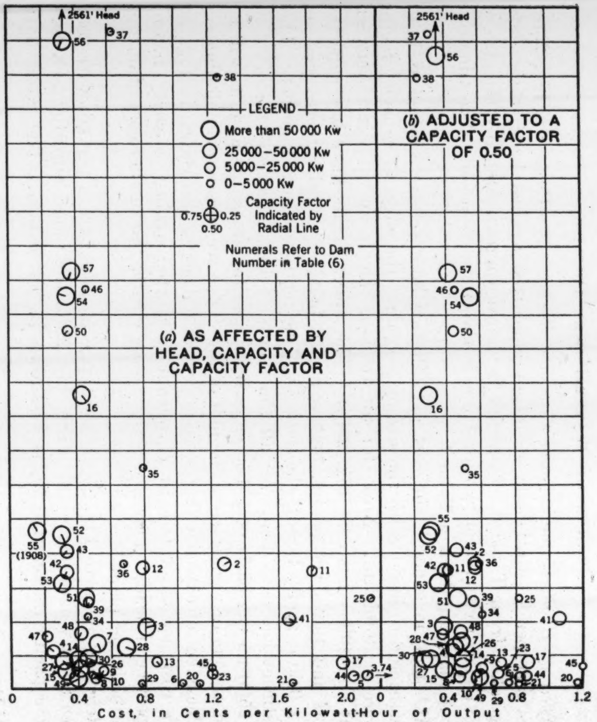

FIG. 25.—COST OF HYDRO-ELECTRIC ENERGY

where the plant is tied in with a load system. In the latter case it is better to credit the hydro-plant with its system peak capacity saving, as has been suggested, and compute the net cost of hydro-electric energy for comparison with steam power fuel saving and attendance.

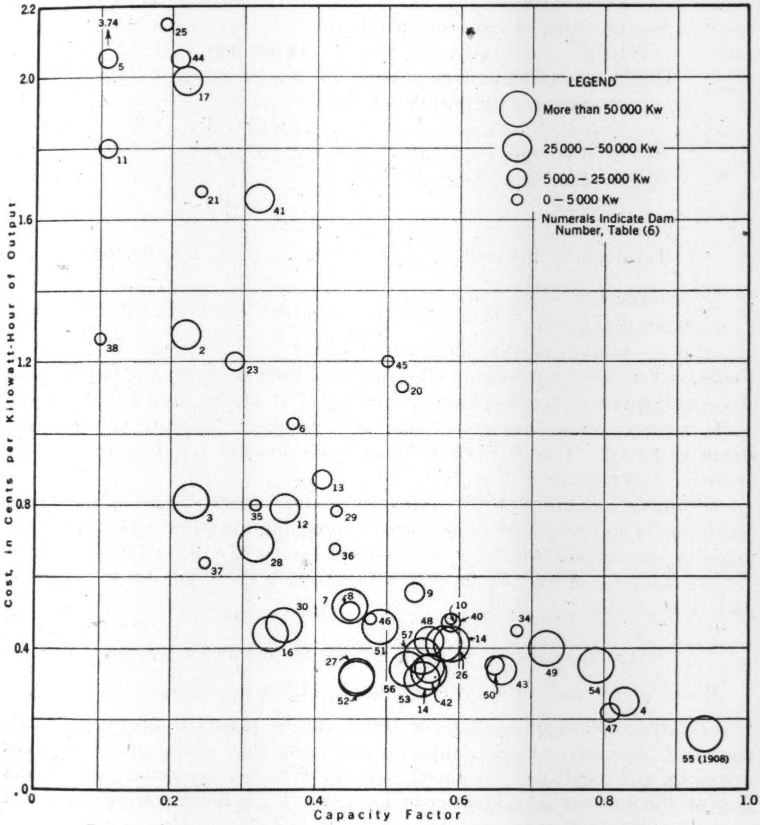

FIG. 26.—COST OF POWER AS AFFECTED BY CAPACITY AND CAPACITY FACTOR

Thus, considering the Conowingo Plant (No. 14, Table 6), in Maryland, on the Susquehanna River (The Philadelphia Electric Company System, September, 1936), to which the following additional data apply:

Average daily low-water, 24-hr power output, in kilowatts	11 000
Peak capacity carried by hydro-electric plant, in kilowatts	210 000
Ratio, $\dfrac{\text{Peak capacity}}{\text{Plant capacity}}$	0.83

By the method suggested, the energy cost per kilowatt-hour of water power would be determined as follows:

Cost of plant		$49 820 000
Credit for saving in steam capacity, 210 000 kw @ $100		21 000 000
Yearly fixed charges on plant @ 10%	$4 982 000	
Credit for saving in fixed charges on steam capacity, $21 000 000 @ 12.5%	2 625 000	
Net fixed charges on plant	2 357 000	
Hydro-plant operation and maintenance	338 000	
Total yearly net cost		$2 695 000

or $\frac{\$2\ 695\ 000}{1\ 300\ 000\ 000 \text{ kw-hr}} = 0.21$ ct per kw-hr, which compares with the cost of fuel plus attendance of equivalent steam power.

In the foregoing analysis no allowance has been made for the higher degree of dependability of hydro-power as compared to steam such that the hydro really replaces somewhat more than an equivalent kilowatt of dependable steam capacity. This is difficult to evaluate exactly but is perhaps of the order of 10 per cent.

Assuming an added 10% saving in steam capacity due to the greater reliability of hydro-power would, in the foregoing example, result in a steam capacity saving of 231 000 kw, and a total saving of $23 000 000, and reduce the energy cost of the water power to about 0.19 ct per kw-hr instead of 0.21 ct per kw-hr.

ADVANTAGES OF WATER-POWER IN A POWER SYSTEM

Water power used in a power system has three advantages:

(1) Hydro-plant units, large or small, can be placed in operation quickly (in a few minutes), which is important and valuable under sudden large load increases, and particularly in emergencies when some large power unit suddenly goes off the line due to accident or break-down. This quick placing in operation is not possible with steam plants.

(2) Additional, or increment, capacity for the hydro-plant with reference to its system peak use is relatively low in cost, as commonly this is limited chiefly to equipment, whereas the increment cost of a steam plant must include the entire plant. Ordinarily, increment costs for water power will be from $40 to $70 per kw of capacity, whereas for steam this will be $80 to $100 per kw.

(3) Hydro-plant units are generally more reliable than steam units, records showing, for modern hydro-plant units, that the non-scheduled outage "when in demand" is so small as to be negligible.

Pumped Storage, Peak Load, Hydro-Plants

This special use of the hydro-plant is fairly common in Europe, but thus far in the United States only two such plants have been constructed: The Rocky River Plant, in Connecticut, and the Lake Keuka Plant, in New York.[11] There are further opportunities for the use of this method of handling peak loads and the development of a pump-turbine unit with two-speed motor-generator unit, as noted by Mr. Frank H. Rogers,[12] adds materially to their practicability and economic feasibility.

Operating and Maintenance Costs, Hydro-Electric Plants

The yearly cost of operation and ordinary maintenance based upon data from forty-five plants in Table 6 is shown on Fig. 27. As will be noted, the median curve shows, for a small plant (1 000 kw), costs varying between about $4.00 and $9.50 per kw yearly and averaging about $7.00 per kw. For large plants (more than 100 000 kw), the cost varies between $0.50 to $0.90 and averages about $0.75. Intermediate costs may be noted by reference to Fig. 27. Variations from the median curve for individual plants are considerable.

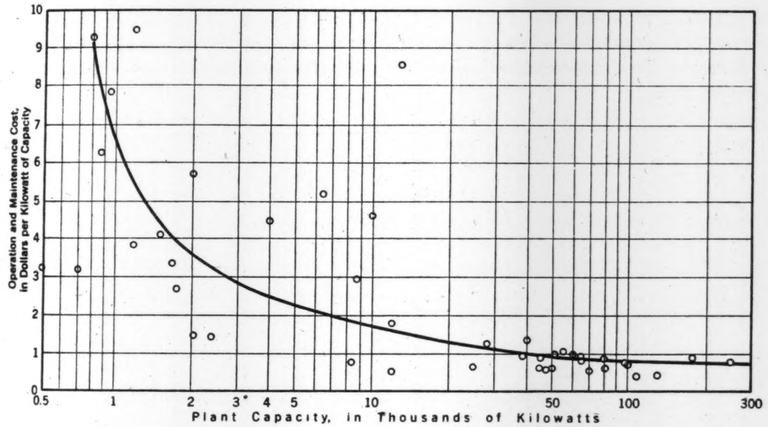

Fig. 27.—Annual Hydro-Plant Operation and Maintenance Costs, in Dollars per Kilowatt of Capacity

Cost of operation and maintenance is also shown on Fig. 28, per kilowatt-hour, plotted against total yearly output. It varies between about 0.20 ct per kw-hr for small plants to about 0.02 ct per kw-hr for large plants, with considerable variation from the median curve. Harmonizing the data from Figs. 27 and 28, data of approximate average operating and maintenance costs have been determined in Table 9. These data are given both as total yearly

40 000	40 000	0.023	....	....	....

costs and, as costs based upon a 0.5 capacity factor, the cost per kilowatt-hour of output. Except for small plants, as has been previously noted, operation and maintenance costs are a relatively small proportion of water power costs.

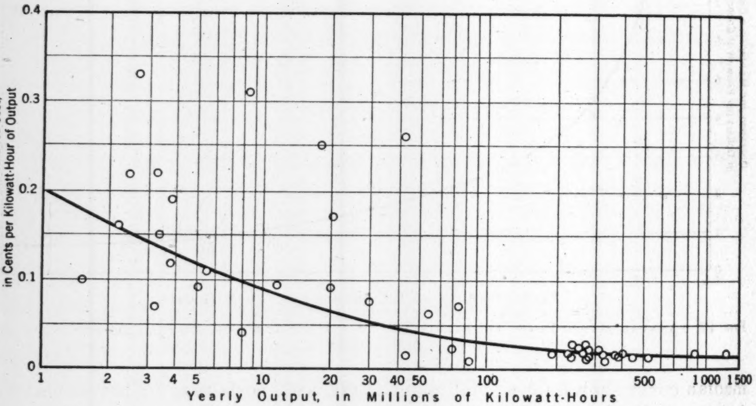

FIG. 28.—OPERATION AND MAINTENANCE COSTS, IN CENTS PER KILOWATT-HOUR OF OUTPUT

FEDERAL WATER POWER PROJECTS

Several large Federal projects for the development of water power have been under way during the past few years. A brief review of these projects in respect to cost appears pertinent in this paper. They include chiefly Boulder Dam, Bonneville, and Grand Coulee in the West, and the projects of the Tennessee Valley Authority in the South.

Boulder Dam (Colorado River).[13]—This is a combined irrigation, power, water supply, and flood-control project, costing about $79 000 000 for the dam and reservoir. The ultimate project contemplates about 1 300 000 kw of capacity under a head of about 530 ft, at a cost of about $43 000 000 for the plant. The total reservoir capacity is about 30 500 000 acre-ft, of which 9 500 000 acre-ft, or about 31%, are reserved for flood control. If the remaining 69% of the cost of dam and reservoir (or about $54 000 000), is allocated to power use, this makes the total cost for power purposes about $97 000 000, or $75 per kw of capacity. The yearly output of firm power is estimated at about 4 billion kw-hr. Fixed charges at 6.5% would be $6 300 000 per yr, operation about $700 000, or $7 000 000 total yearly cost, at about 0.17 ct per kw-hr (without transmission).

Bonneville (*Lower Columbia River*).[13, 14]—This is essentially a water power project, but includes provision for irrigation. The ultimate project contemplates 432 000 kw of capacity under a head of about 54 ft, at a total cost of approximately $65 000 000, or $150 per kw of capacity. The fixed charges (at 6.5%) will be about $4 200 000, the operation and the maintenance cost about $300 000, or a total yearly cost of about $4 500 000, which is about 0.22 ct per kw-hr for an output of about 2 billion kw-hr per yr (without transmission).

Grand Coulee (*Upper Columbia River*).[13, 15]—This is a water-power project, although there is a supplemental irrigation project. The complete project is estimated to cost about $196 000 000, with about 1 900 000 kw of capacity, or slightly more than $103 per kw under a head of about 300 ft. The ultimate yearly output will be approximately 9 billion kw-hr; fixed charges (at 6.5%) $12 700 000; operation and maintenance, $1 000 000; or a total yearly sum of nearly $14 000 000, which is about 0.15 ct per kw-hr (without transmission).

Tennessee Valley Authority (*Tennessee River*).[16]—These projects include a comprehensive development of the Tennessee River by relatively high dams for the combined objective of creating power, flood control, and navigation.

Eleven major projects are planned which, in general order, going up stream are: Gilbertsville, Pickwick, Wilson, Wheeler, Guntersville, Chickamauga, Watts Bar, Coulter Shoals, Norris, Fontana, and Fowler Bend. Ultimate power installation includes about 1 800 000 kw of capacity and nearly 6 billion kw-hr yearly of primary power.

Power development alone (not including dams, reservoirs, etc.) will cost about $135 000 000, or $75 per kw of capacity. The total cost of the eleven projects, including power development cost, is estimated at about $520 000 000, or if all is charged to power, about $290 per kw of capacity.

For the ultimate development the fixed charges (at 6.5%), operation and maintenance, and total power costs would be as shown in Table 10. The cost of this water power will thus depend upon the proportion allocated to flood and navigation benefits. If dams and reservoirs are entirely allocated to these two items, the water power will cost about 0.20 ct per kw-hr; if they are entirely allocated to power, the cost will be about 0.60 ct per kw-hr.

The cost of water power from the four Federal projects is summarized in Table 11(*a*). In comparing these costs of power with those from the plants

Lilienthal and Arthur E. Morgan, M. Am. Soc. C. E., pp. 113–292; Second Deficiency Appropriation Bill, T.V.A., Committee Rept., 75th Cong., 1st Session, 1937, Testimony of Arthur E. Morgan, pp. 339–451.

TABLE 10.—COST OF PROJECTS BY TENNESSEE VALLEY AUTHORITY

Item	Basis	
	Power development cost alone ($135 000 000)	Total cost ($520 000 000)
Fixed charges, in dollars	8 800 000	33 800 000
Operation and maintenance cost (including reservoir operation), in dollars	2 200 000	2 200 000
Total yearly	11 000 000	36 000 000
Cost, in cents, per kilowatt-hour (6 billion kilowatt-hours)	0.183	0.60

in Table 6, it must be kept in mind that fixed charges for the Federal water power projects were taken at 6.5% whereas the others are on a 10% basis. In Columns (6) and (7) of Table 11(*a*) a comparison of costs with these two bases is given.

TABLE 11.—COST SUMMARY

Item No.	Plant	Head, in feet	Ultimate plant capacity, in thousands of kilowatts	Unit capacity, in thousands of kilowatts	Annual output of ultimate project, in billions of kilowatt-hours	Cost, in Cents per Kilowatt-Hour, for Fixed Charges of:		Allocation; cost of dam and reservoir
						6.5%	10%	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
	(*a*) Federal Water-Power Projects							
1	Boulder Dam	530	1 300	80	4.00	0.17	0.26	31% to flood control
2	Bonneville	54	432	43	2.00	0.22	0.34	To power
3	Grand Coulee	300	1 900	105	9.00	0.15	0.23	To power
4	Tennessee Valley Authority	40 to 400	1 800	23 to 45	6.00	0.18 to 0.60	0.26 to 0.90	To navigation and flood control To power
	Totals	....	5 432	....	21.00	....	....	....
	(*b*) Large Water-Power Plants Given in Table 6							
5	Conowingo	89	252	36	1.30	....	0.41	To power
6	Safe Harbor	55	178	30	0.88	....	0.33	To power
7	No. 52	454	70	35	0.28	....	0.31	To power
8	No. 53	315	81	27	0.39	....	0.31	To power
9	Waterville	860	108	36	0.33	....	0.44	To power
	Total, or average	....	....	....	3.18	....	0.36	....

The Federal plants are also quite large. It is to be noted that their total output would be about 50% of the entire public utility water-power use in the United States for 1936. Compared on the basis of 10% fixed charges, the cost per kilowatt-hour is only little less for these large Federal projects than for some of the large plants listed in Table 6, such as Conowingo, Safe Harbor, Waterville, and Nos. 52 and 53 in the West (see Table 11(*b*)). In the case of the Federal projects other than Boulder Dam the use or marketing of the power must be deferred for an indefinite time, so that an added item of accrued carrying charges should be included. This has not been allowed for in computing Table 11(*a*).

UNDEVELOPED HYDRO-ELECTRIC POWER

The total developed water power in the United States as of January 1, 1937, was about 17 million hp, or approximately 12 million kw.

The total potential water power (including developed power) available 90% of the time was about 43 million hp, or about 30 million kw. The ten leading States in this respect are:

State	Horse-power, potential water power (available 90% of time)
Washington	8 800 000
California	4 600 000
Oregon	4 400 000
New York	4 300 000
Arizona	3 700 000
Idaho	2 700 000
Utah	1 500 000
Montana	1 300 000
Tennessee	1 300 000
Alabama	900 000
Total, ten States	33 500 000

Thus, about three-fourths of the potential water power is found in these ten States (all but three of which are in the West).

It must be kept in mind, however, that the plant capacity would greatly exceed the minimum, or 90%, power, and probably 80 million hp or more of capacity would be required to utilize all the available water power in the United States. Of the total output of public utility plants in the United States in 1936, of about 114 billion kw-hr, about 41 billion kw-hr, or 36%, was hydro-electric power.[17] By general districts this was distributed as follows:

District	Billion kilowatt-hours	Percentage of total
Atlantic Coast States	17.4	43
Central States	7.8	19
Mountain States	3.3	8
Pacific States	12.5	30
Totals	41.0	100

Although many of the better sites for the development of water power have been utilized, there are still many sites that may be commercially utilized as the market for power is extended. Even in the Atlantic Coast District, where the present use of water power is greatest, there are still potential opportunities for comprehensive river developments for power, including storage, as well as for redevelopment in some cases.

ACKNOWLEDGMENTS

This paper has been made possible through the generous contribution of cost and other supporting data for many water power plants.

Acknowledgments are made to the Federal Power Commission, through Thomas R. Tate, Chief of the Division of Power Resources and Requirements, U. S. Department of the Interior, for access to, and use of, its project files and for its kind assistance. Many engineers and executives of the public utility companies have generously responded to the request for data relating to hydroelectric projects. Mr. Arnold H. Engborg, of the writer's Office Staff, has also assisted in the preparation of this paper.

COMBINED ENERGY GENERATION

By Ezra B. Whitman,[18] M. Am. Soc. C. E.

No attempt will be made in this paper to consider anything but the cost of combined steam and hydro-electric generation although the same principles must be followed in determining the cost of any other combination. The cost of combined energy generation will vary with every combination, and it is not possible to determine such cost for one combination and apply it to another, although the method of determining such cost may be the same in each case. This paper, therefore, will discuss principally the methods that must be followed in determining the cost of combined energy generation and the variable factors that affect such cost.

The Development of Combined Energy Generation

The first plants for the generation of electricity by water power were constructed about 1890 and the concept of the hydro-electric plant in energy generation has undergone many changes since that time. These first plants were usually the sole source of power. This being the case, they were constructed with a capacity of generating equipment for utilizing only the minimum flow of the stream. This was the firm power that could be depended upon throughout the year. They were built in those sections of the United States where fuel costs were high and where water power was available. A number of them were built in California before the discovery of oil and gas in this section.

In order to increase the amount of firm power, storage was resorted to and large storage reservoirs were built in conjunction with the hydro-plants so that the water could be drawn upon at times of minimum flow.

At other plants, where the cost of storage was prohibitive, steam plants were built in conjunction with the hydro-plants. As the larger systems, covering vast sections of the country were developed, the hydro-plants became generating units in these systems in which both steam and water were used as sources of power.

Types of Plants with Combined Energy

At present (1938) there are some plants which are mostly hydro-electric, with steam plants to be used during times of minimum flow. Such plants are the simplest ones for which to determine the cost of the combined energy generation. Many of them began to furnish power entirely from water, but as the power requirements grew, they could not supply the demand at the time of low flow, and steam plants were installed to meet these demands at such times.

---

[18] Cons. Engr. (Whitman, Requardt & Smith), Baltimore, Md.

The opposite combination is that in which steam plants were first built to furnish the required power. The cost of furnishing peak power by steam is quite high, due to the fact that the boilers must be kept hot, and steam-generating units must be prepared to pick up the peak load during the day as the load increases; and when the load diminishes toward nightfall, the steam units are put out of service, but kept in condition so that they can be placed in operation again as the load increases. If there is a water-power site available that can be developed within a reasonable cost, it is much more economical to carry the peak loads by hydro-electric generation than it is with steam generation, and, therefore, a number of plants have been developed in which water is combined with steam for the purposes of carrying the peak loads.

The third type of combination is found in those plants in which large hydro-electric installations can be made and operated in connection with the steam plants so that the water-power plants, at times of high flow, carry the base load and the steam plants carry the peaks; and, during periods of low flow, the water-power plants are used to carry the peak while the steam generation carries the base load.

FIRM CAPACITY OF WATER-POWER PLANTS

In the early days of hydro-electric development, the firm capacity of a water-power plant was considered to be only the power that could be generated by the minimum flow of the stream. If the generating capacity of the plant was greater than could be operated at times of minimum flow, this capacity was looked upon as secondary power. Its sale was quite limited, and it could be used only by such industries as could afford to close down during the times of low flow.

With the combination of steam and hydro-electric power that has developed in recent years, the firm capacity of a water-power plant is looked upon in an entirely different sense. It is possible now to use practically all the power that can be developed in a water-power plant in a large system, so that this distinction between firm and secondary power no longer exists. At present, what might be termed the firm capacity of a hydro-plant can be defined as that part of the total installed capacity that is capable of doing the same work on that part of the load curve of the system that a steam plant could perform. This firm capacity varies with the shape of the load curve of the system that is being supplied by both the steam and the water. It does not necessarily come at the time of minimum flow of the stream, which might come in August or September when the load on the system is not the peak. Such a peak usually occurs during December, and in order to determine this firm capacity, the minimum stream flow for that month should be used as a basis for determining the firm capacity of the plant.

FACTORS TO BE CONSIDERED IN DETERMINING THE COST OF COMBINED ENERGY GENERATION

The cost of steam generation and the cost of hydro-electric generation have been covered by two other papers in this Symposium but it will be necessary to review to some extent the principles of determining such cost in order to show how the cost of combined energy generation must be determined. The first factor to be determined is the construction or capital cost of both the steam plants and the hydro-plants used in the combination.

There is a wide variation in the cost of modern steam plants. In the 1937 report of the Power Authority of the State of New York, the costs of modern steam-generating stations are shown to vary from $62 per kw to $151. On the other hand the cost of hydro-plants will vary from about $125 per kw of installed capacity to $350, and more. As this first cost of both the steam and the hydro-plants is a large element in determining the cost of the combined energy generation, it can readily be seen that it is impossible to ascertain the cost of combined energy in one system and use that cost as a measure of the cost of the combined energy in another system.

These wide variations of first costs in both steam and hydro-plants may be thoroughly justified by the conditions under which the different plants are built. Steam plants built along the Ohio River, such as those serving Cincinnati, Ohio, and adjacent areas, using the river water for condensing purposes, will be much more expensive than a plant constructed in Baltimore, Md., which uses the tidal waters for condensing purposes. At times of flood the Ohio River rises to a height of 70 ft above the normal river stage, and the foundation expense and the cost of getting the condensing water for such a plant is many times what it would be in Baltimore where the tidal range is ordinarily about 13 in., with a maximum of approximately 5 ft.

With hydro-plants, although the cost of the power-house machinery is comparatively constant, the cost of the dam construction and lands will depend upon the topography of the particular site. Then, there is the question of rebuilding roads that are flooded and, in a number of cases, relocating railroads, telegraph and telephone lines, and the flooding of villages that must be purchased.

It is necessary to determine the construction cost of both the steam plants and the hydro-plants used in the production of combined energy, in order that the fixed charges (which are a large part of the cost of energy generation in either type of plant) may be determined. These fixed charges are: (1) The cost of money; (2) taxes and insurance; and (3) depreciation and obsolescence.

The cost of money with a private company depends very largely upon the financial condition of that company. Large companies that have been soundly administered can secure their money at a much cheaper cost than is possible for the smaller companies and particularly for a new untried project. Although it is true that the large private companies can sell their bonds at a much lower rate of interest at present than was possible before the depression, on the average, the private companies have raised only about one-half their money by the issuance of bonds. An investigation of twenty-seven large utility companies shows that 51.3% of the total capitalization of these companies was the funded debt, and the other 48.7% of the capitalization was raised by the sale of either preferred or common stock. Before the depression, it was not at all unusual for companies on the average to pay between 7% and 8% for the money used for capital purposes. At present (1938), it is doubtful whether private companies could raise both senior and junior securities at a cost of much less than 7 per cent.

Taxes and insurance vary in different localities, but on the average for steam plants about 2% is usual. Hydro-plants are usually built in the country districts and have lower taxes, which will vary from 0.5% to 1.5%, with an average of about 1 per cent. In some States special taxes are placed on private utilities developing water power and, therefore, the taxes are much higher.

Depreciation and obsolescence are much heavier on steam plants than on hydro-plants. The latter have reached a point at which the machinery is already capable of operating at an efficiency of more than 90 per cent. With steam plants the development of the art has been very rapid since the beginning of the Twentieth Century. The thermal efficiency of steam engines has increased from about 18% to about 36 per cent. Taking into account both physical depreciation and obsolescence of steam plants, it is usual to allow approximately 2.5% to 4% for this item, with an average of about 3.5 per cent. With regard to the hydro-plants, there is little or no depreciation on lands and heavy structures such as dams, the greatest depreciation occurring in connection with the hydraulic and generating equipment. For hydro-plants this item is usually estimated to vary between 0.5% to 1.5%, with an average of approximately 1 per cent.

It is usual, therefore, to compute fixed charges at the present time for steam plants as approximately 12.5%, although these charges have been computed as low as 11% and as high as 15 per cent. With regard to the hydro-plants, at present the average fixed charges would be about 9% although they have been as low as 7% and as high as 11 per cent.

Operating and Maintenance Costs

In order to determine the cost of combined energy generation, not only must the construction cost be secured, but the operating and maintenance costs of both the steam and the hydro-plants must be determined. Again, these costs are widely variable. With steam plants, the largest single item is the cost of coal, which varies from approximately $1.75 at the mouth-of-mine plants to $5.00 or more in regions situated at long distances from the coal fields. The writer will not attempt to describe the many elements of the cost that enter into the operating and maintenance costs of steam plants. One of the controlling elements is the load factor and the shape of the load curve. Load factors on different plants vary from 35% to 70% which causes a wide variation in operating costs even if the two plants are identical, and both of them are able to secure coal at the same price.

Transmission Costs

Another element that enters into the cost of power delivered at the load center is the cost of transmission. As a rule, the steam plants can be built in the load centers, although this is not always the case. With hydro-plants, the rule is the opposite, most of them being built at a distance from the load center; and these transmission costs, where they occur, must be computed against either the steam or the hydro-plant in determining the cost of combined energy generation at the load center.

INCREMENT COSTS OF HYDRO-ELECTRIC PLANTS

It is not unusual in building hydro-plants to make provision for the future installation of additional units. As the load on the system grows, it becomes possible to utilize more of the flow of the river advantageously than might be possible at the time that the plant was originally constructed. The cost per kilowatt of installing such units is only a fraction of the cost of the original installation, taking into account the cost of lands, dam, and other elements over and above the actual power-house construction, with the water-wheels, water turbines, and generating and transforming equipment.

THE PROBLEM OF DETERMINING THE COST OF COMBINED ENERGY GENERATION

The cost of steam generation is the yardstick for measuring the value of hydro-electric generation. The studies that are made to determine the cost of combined energy generation are practically the same as would be made by a company that was faced with the problem of determining whether it would be better to develop a hydro-project or add additional steam capacity to its generating equipment.

The question that must be answered is whether the proposed plant will reduce the cost of power? If this can be answered in the affirmative, the plant will be built; otherwise, additional steam equipment will be added. In many modern power systems, in which both steam and water power are used as sources of power generation, the two sources are not competitive but are really complementary sources of power supply. It has frequently been found that, with the combined sources of energy generation, the power can be delivered to the customer more cheaply than would be the case had the company depended upon either steam alone or water power alone.

This may be true, where the cost of the water power is considerably more than the cost of that part of the power which is generated by steam. There have been occasions in which it was very difficult to convince public service commissions that it was in the interests of the consumers to use hydro-generated power at a considerably higher cost per kilowatt-hour than the steam power being generated in the same system. Of course, the economic use of water power, even if it costs more than the steam, is justified by the fact that it will replace that part of the power in the load curve which comes on the peaks and which it would be more costly to generate by steam. Many large steam systems have modern base-load plants that produce electricity at a low cost. The older plants, which are more expensive to operate and cost more for the production of a kilowatt-hour of power, are used only for peak and emergency purposes. The actual power produced in such old steam plants is small and may be only a small percentage (or none) of the total annual production; yet their capacity in the system is required for peak and emergency service and if the company did not have such plants, it would be necessary to build them, or new plants of equal capacity. Under these circumstances, it is much more economical to hold these old plants ready for service than to build complete new equipment for this use.

In some of the large systems, such as the Philadelphia Electric Company in 1925, there were eight steam plants and in 1923 the smallest and least economical of the plants was called upon to produce only 39 000 kw-hr out of a total of nearly 2 000 000 000 kw-hr. In a conversation with the president of one of the large Eastern power companies, for which there had been installed in about 1918 or 1919 several 20 000-kw steam-generating units, the writer was told that the company had not operated these units for several years and hoped that it never would. Nevertheless the sources of supply were such that had there been an interruption to the one of the larger sources, it would have been necessary to have started these units, which will be held in the system as a reserve for many years in the future.

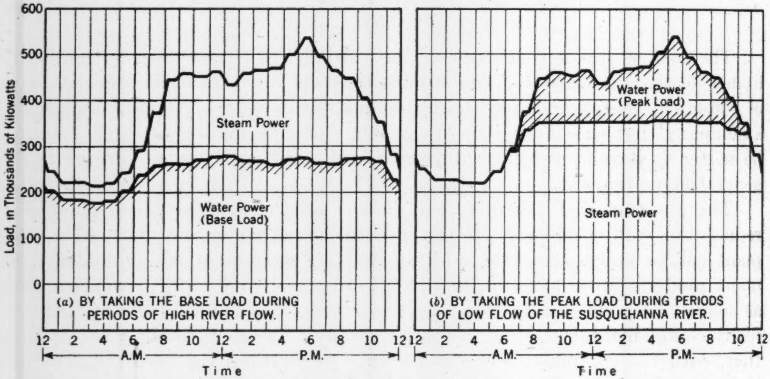

FIG. 29.—COMBINED 24-HOUR LOAD CURVE OF BALTIMORE, MD., AND WASHINGTON, D. C., SHOWING HOW SYSTEMS ARE SERVED BY WATER POWER FROM HOLTWOOD AND SAFE HARBOR PLANTS OF PENNSYLVANIA WATER AND POWER COMPANY

Fig. 29 illustrates how the modern water-power and steam-power plants are used in a complementary manner. Fig. 29(*a*) shows how the water power would be used in a period of high flow of the river to carry the base load and Fig. 29(*b*) shows how the water power is used at a period of low flow to carry the peak loads. This "hydro" is supplied from the Holtwood and Safe Harbor Plants, owned by the Pennsylvania Water and Power Company, and the Safe Harbor Water Power Corporation, respectively. The Holtwood plant was built before 1913 and the Safe Harbor plant about 1932. When the second plant was completed, Baltimore was not inter-connected with Washington, D. C. Within the past few years, however, this inter-connection has been made so that these two plants serve both Baltimore and Washington. With this increased load, the firm capacity of the combined hydro-electric plants has been considerably increased and thereby its value to the two systems is greater than it was when Baltimore alone was served.

In order to demonstrate the methods of arriving at the cost of combined energy generation, the writer presents very briefly, herewith, the method used in determining the value of the Conowingo Plant to the Philadelphia (Pa.) Electric System at the time when this project was being considered by the Maryland and the Pennsylvania Public Service Commissions.

THE ECONOMIC VALUE OF THE CONOWINGO WATER POWER IN THE PHILADELPHIA ELECTRIC SYSTEM

In 1925, application was made to the Maryland Public Service Commission and the Pennsylvania Public Service Commission for approval of the building of the Conowingo Power Plant on the Susquehanna River. The plant proposed contemplated the installation of six 50 000-hp turbines and six 40 000 000-kw generating units. This site had first been considered as a source of power more than a generation ago with Baltimore as the ultimate market for such power. Although Baltimore could have absorbed the power generated by the low flows of the river, it was not possible for Baltimore to absorb the power that could be generated economically at this site during the four months of the year when the stream flow would make it possible to operate the contemplated plant at full capacity. Philadelphia, however, with a much larger market for the power, offered the opportunity for the economic development of this site. Even with that city, it was estimated that it would not be until 1930 that the full economic value of this plant could be realized with the installation of six 40 000-kw turbines.

The study included the possibility of installing four more 40 000-kw units. The stream flow would provide for full operation of these ten units for approximately 20% of the time.

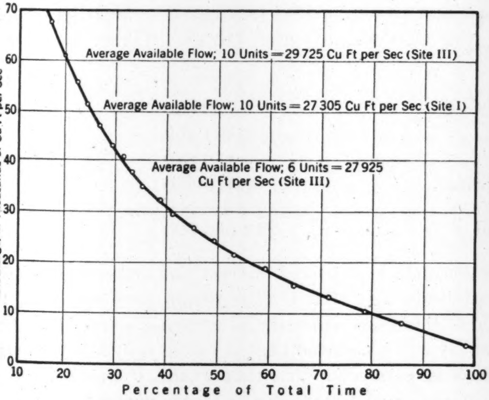

FIG. 30.—CONOWINGO DEVELOPMENT, DURATION OF FLOW CURVE, SUSQUEHANNA RIVER AT SITE III, 1891–1922

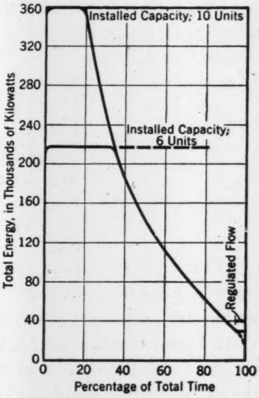

FIG. 31.—POWER DURATION CURVE, PROPOSED HYDRO-ELECTRIC DEVELOPMENT, SUSQUEHANNA RIVER, NEAR CONOWINGO, MD.

Stream-flow records were available from 1891 to 1923 and the stream duration curve shown in Fig. 30 was prepared from the flow records. A power duration curve from the data computed on an 85% over-all efficiency of the water-power plant to and including the high tension bus-bar, was also prepared (see Fig. 31).

The total rated capacity of existing steam plants in Philadelphia at the time of the hearing was 476 480 kw and the load factor on the Philadelphia Electric System in 1923 was 43.8 per cent. In 1924, it was 44.8 per cent. It was estimated that by 1930, the peak, maximum, co-incident load for the steam and water power plants would be 600 000 kw and that the steam plants could carry 405 000 kw and the water-power plants would carry 195 000 kw of this peak.

In 1930, it was also estimated that the average or typical flow-year would generate, at the hydro-electric plant, 1 278 000 000 kw-hr and that 90% of this generated power could be delivered to the system in Philadelphia, or 1 150 000 000 kw-hr. For the same year it was estimated that the steam plants would generate 1 080 000 000 kw-hr. In other words, the hydro-electric plants would produce 51.5% of the total power required and the steam plants would produce 48.5 per cent.

At that time eight steam plants were being used in Philadelphia in the generation of electricity and the maximum demand on each of these stations and the kilowatt-hours generated were shown for 1923 and 1924. Typical, daily, load curves were chosen to show the approximate variations during the year, arriving at a typical curve for each month. Stream-flow tabulations were made on a monthly basis of the average flow within the plant capacities for six and ten units, and the power available from these flows was fitted to the load curves so as to obtain the most economical adjustments between the hydro-electric and the steam plants.

Computations were then made assuming that new steam-generating equipment was built instead of the Conowingo water power. These costs were divided as follows:

Fuel	$ 9 722 000
Labor	1 394 100
Supplies	139 880
Maintenance	1 410 520
Total	$12 666 500

This cost, of course, does not include any fixed charges and amounted to 5.68 mills per kw-hr. It was estimated also that if Conowingo were not built, it would be necessary to build 250 000-kw capacity of steam-generating plant. With Conowingo constructed, it was estimated that it would only be necessary to build 100 000 kw of generating capacity. In other words, it was estimated that Conowingo would take the place of 150 000 kw of steam generation, which would cost $135 per kw to construct, or $20 250 000. Fixed charges saved on a steam plant were estimated to amount to 11.5% of this amount, which is $2 330 000. The annual charges on fuel, supplies, and equipment which were saved were estimated at $82 000.

These 150 000 kw of steam capacity, which the water-power plant could replace, were determined from Fig. 32, showing the estimated average week-day load curve for December and that part of the load which could be served by hydro-electric plants with the minimum flow of the river. This diagram also shows that with a minimum flow, the hydro-plant could be utilized to take care of 153 000 kw of the demand on the system. It was assumed, therefore, that the firm capacity of the Conowingo Plant in the Philadelphia Electric Company System would be 150 000 kw. The estimated average week-day load curve for the wet month of March, 1927, is shown in Fig. 32(*b*). As a result of these investigations, the following tabulation was prepared to show the value of the hydro-plant in the Philadelphia Electric Company's System, compared to what the cost would have been had that Company constructed new steam generation instead of the Conowingo Hydro-Plant:

Cost of producing all power requirements from steam (1930)		$12 666 500
Cost of steam power after hydro-power comes in (1930)		7 163 000
Operating saving from hydro-electric energy		$ 5 503 500
Fixed charges on $20 000 000 representing 150 000 kw saved in steam-plant investment		2 330 000
Charges on saving in coal and equipment supplies from use of hydro-electricity		82 000
Total representing what the Company could afford to pay for the hydro-plant		$ 7 915 500
Cost of Hydro-Power:		
Rentals	$4 580 000	
Operating expenses, taxes, and depreciation on hydro-plant and lines	1 430 000	
Operating expenses, taxes, and depreciation on investment in Company territory in relation to hydro-electric generation	1 126 000	$ 7 136 000
Remainder representing the saving from use of hydro-plant		$ 779 500

As the hydro-plant was estimated to furnish 1 150 000 000 kw-hr per yr, the saving on this part of the current generated at the Conowingo Hydro-Plant would amount to 0.7 mill per kw-hr or, on the total power generated of 2 230 000 000, the saving would be approximately 0.36 mill. The total cost of the water-power current delivered in Philadelphia was estimated at 6.2 mills per kw-hr. The total cost of the steam generation of all the current was estimated to cost 5.68 mills per kw-hr; but by utilizing the hydro-power for peak service during the dry flow and base-load service during the wet months, the cost of the combined energy generation was reduced nearly $800 000 per yr, although the hydro-power by itself cost 6.2 mills as compared with the 5.68 mills if all the power had been generated by steam alone. This is a typical illustration of the economic advantage of combining steam and hydro-electric generation.

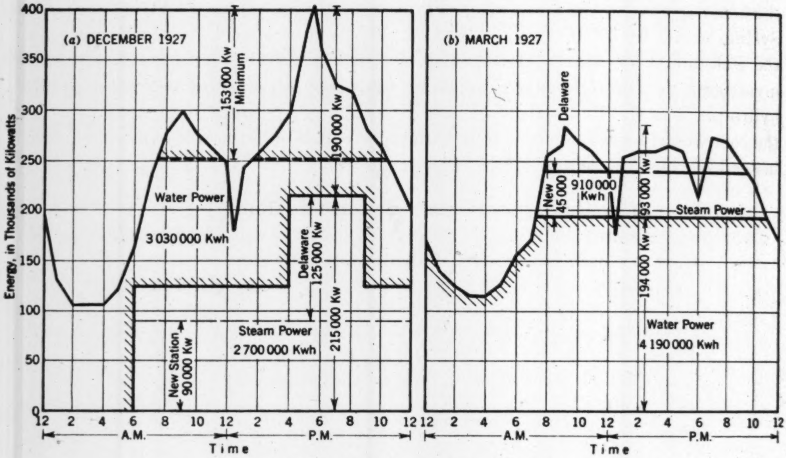

FIG. 32.—ESTIMATED AVERAGE WEEK-DAY LOAD

FEDERAL HYDRO-PROJECTS

Federal water-power projects were started in the area covered by the Tennessee Valley Authority (TVA) with a view to providing "yardsticks" to determine whether the rates charged by private companies were reasonable. In the TVA case before the Alabama Public Service Commission, the only plant under consideration was the plant at Wilson Dam, Muscle Shoals, Ala. A steam plant costing about 12.25 million dollars was built during the World War and the hydro-plant was started; but until 1920 only approximately 3 million dollars had been spent. The project was completed in 1926 at a total cost of about 47 million dollars so that the hydro and steam plant combined cost about 60 million dollars.

It is true that the steam plant was built under war conditions, but the hydro-plant was not more than well started before 1920, and its construction was completed during the same period that a great number of private plants were built. It was testified that the Government would pay only 3% for its money, therefore, the rate of return required would be only this rate; whereas, private companies had been compelled to pay about 7% for their money. Although many of the private companies had spent considerable sums of money to provide locks and canals for navigation purposes, they had always been forced to absorb this expenditure in their capital investment for developing electricity. At Wilson Dam, one-third the cost of the entire project was charged to navigation, another one-third was charged to national defense, leaving less than 20 million dollars as the rate base on which the Government would pay 3 per cent.

With regard to the national defense, it is unquestionably true that the private power plants throughout the country engaged in furnishing power for a great number of defense projects have a value for the purposes of national defense in the same sense as the plant at Muscle Shoals; yet no credit was given to the private plants for national defense. In a number of Federal projects, there will also be allocations of the cost of the project, not only to navigation and national defense, but to flood protection, soil erosion, irrigation, and possibly for other uses.

In the aforementioned TVA case, it was also testified that the Government would pay the taxes just as a private company did, but the taxes that the Government proposed to pay were only 5% of the annual income from the plant, whereas it was shown that the private companies were paying taxes nearly three times this 5 per cent.

In practically all the operations in connection with the production and distribution of the electricity, the Government had estimated the governmental costs much below what these corresponding costs were for private companies. No private company would ever have built the great hydro-plants that have been built or are being built by the Government in the valley of the Tennessee River without first making studies as to how this power could be absorbed by the available market, in the same way that the studies were made in connection with the Conowingo Power Plant. If any such studies have ever been made, the writer has certainly never seen nor heard of them.

As the fixed charges on the hydro-plant are by far the greater part of all the charges against the cost of hydro-generation of electricity, the fact that the Government will begin with only 3% as the cost of the money, as against twice this rate for private companies, will give the Government water power tremendous advantage over any project that could be built by private capital. The Government is also in a position such that it can wait for the development of a market to absorb power which it generates and any deficits can be made up by taxation. Private companies are not in a fortunate enough position to be able to spend tremendous sums of money on projects which it may take years to develop to the point where they will pay a sufficient return on the capital invested to attract private capital.

The writer is convinced that it is useless to bicker about the comparative costs of hydro-power and steam power and of privately operated plants and Government-owned and operated plants if the greatest good of all the people of the country is to be served. After all, the cost of generating power is the smallest part of the cost of delivering the power to the customers and particularly the domestic customers. At the most, what is being argued about is a few mills per kilowatt-hour in the cost of the current as finally delivered to the customer. If the Government and the private companies would only sit down together and develop a plan for the most economical utilization of their combined power plants, it would be possible to serve the customers who may be within the territory that can be served by the Government hydro-plants to the advantage, not only of the customers, but also in such a manner that the investments by the private companies will not be greatly impaired or destroyed. Should the Government go into the TVA area and take from the private companies such cities as Knoxville, Tenn., Chattanooga, Tenn., Nashville, Tenn., Memphis, Tenn., and Birmingham, Ala., this would render useless much of the property of the private plants now serving these communities and would undoubtedly destroy the value of the investments by hundreds of thousands of individuals who own securities in these private companies.

The writer hopes sincerely, that some method may be found whereby the people will get the benefit of the Government plants and that the property of the private companies may be saved for their owners.

DEPRECIATION AND OBSOLESCENCE

BY MAURICE R. SCHARFF,[19] M. AM. SOC. C. E.

SYNOPSIS

Depreciation should be used as a generic term for the effects of physical deterioration, obsoleteness, inadequacy and change in use or in demand, and requirement of public authority. The writer treats the engineering aspects of each of these causes of depreciation, and suggests that engineering study offers the greatest hope of progress toward their better understanding.

The determination of annual depreciation expense is then discussed. It is pointed out that such determinations heretofore have customarily been based on one or the other of two erroneous assumptions—either that all the causes of depreciation became effective in proportion to the passage of time, in accordance with a straight line or sinking-fund formula; or, that none of these causes became effective with the passage of time, or prior to the retirement of the property. The writer suggests that a rational engineering approach would recognize that some causes of depreciation do progress with the passage of time, and that others do not.

A procedure for the application of this concept to the determination of annual depreciation expense is summarized briefly, and its relation to the cost of power in competitive industry, public utilities, and governmental projects is discussed.

An opportunity is afforded the Engineering Profession to clarify the subject of depreciation by discussion of its engineering aspects. The writer proposes that civil engineers invite the co-operation of engineers in all branches of the profession in carrying out such a program.

INTRODUCTION

About a quarter of a century ago a Special Committee of the Society undertook a study of the problem of valuation of public utilities, the final report[20] on which has achieved recognition as an important contribution to the literature of this controversial subject. Not that this report ended the controversy. On the contrary, it has raged unabated to the present time, and has lost none of its vigor—as has been demonstrated by the renewal late in 1937 of the old debate over the relative merits of "prudent investment" and "fair value" as a basis for public utility rate-making. One chapter of the report was devoted to the subject of depreciation; and although twenty years have elapsed since its publication, one can still agree with the opening sentence of that chapter, in which the Committee states:[21] "Perhaps there is no single subject in connection with valuation that has caused more trouble than depreciation."

---

[19] Cons. Engr., New York, N. Y.

[20] *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), pp. 1311–1581.

On re-reading this report, in preparation for this paper of the cost of depreciation and obsolescence in energy generation, the writer has had the impression that if depreciation had been more clearly recognized at that time as the result of the actual incidence of specific causes, the Committee would have devoted more attention to consideration of the engineering facts regarding these causes and their effects, and would have placed less emphasis upon the relative merits of mathematical formulas for relating depreciation solely to the passage of time. Much of the discussion of the subject in the past, particularly that by accountants and economists, has proceeded from the assumption that depreciation was a simple function of cost, time, and the interest rate. More attention has often been paid to the shape of the curves and the forms of the equations for these functions than to the facts which they purported to explain.

It is the writer's proposal that depreciation be used as a generic term for the effects of several categories of causes. He proposes to discuss this suggestion in somewhat general terms, with reference to cost of energy generation only for purposes of illustration, conceiving this to be the most helpful contribution he can make to this, the Second, Symposium on Power Costs.

The categories of causes of depreciation usually listed in discussions of the subject include deterioration, wear and tear, obsoleteness, inadequacy, change in demand, change in use, and requirement of public authority. The mere enumeration of these causes, however, suggests that their effects cannot be expressed as any simple function of the passage of time, because it is common knowledge that an older unit of property or equipment may be, and often is, less deteriorated, more efficient, safer or more reliable, and less affected by change in demand, change in use, or the requirement of public authority than a similar unit of property or equipment of lesser age.

It is true that the incidence of these causes are events that occur in the universal framework of time, and that the effects of some of them are continuous, and sufficiently regular to permit formulation as simple functions of time. In most cases, however, the incidence of these causes is discontinuous, irregular, and even fortuitous with respect to time; and the engineer recognizes that their effects can be better expressed in terms of functions of physical and chemical change, abrasion, rupture, change of form or dimensions, loadings, stresses and moments, capacities, demands and uses, efficiencies, lost time accidents, service interruptions, competition of substitute services, etc., than in terms of the complicated, high-order functions that would be required to express their relation to the passage of time.

It is most fitting, therefore, that the Engineering Profession should devote attention to the development of a better understanding of the causes of depreciation and the measurement of their effects. If progress can be made in this direction, it may yet come about that accounting for costs and profits in industry and finance, and regulatory practices relating to public utilities will be brought into harmony with the facts relating to depreciation. It has too often been assumed that the meaning of depreciation is dependent upon accounting and regulatory policies and practices.

---

[21] *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), Chapter VI, p. 1448.

Part of the confusion of the past has been due to the fact that in accounting and finance, depreciation has been looked upon as synonymous with amortization of investment. It is a sound financial principle that the value of a capital investment is equal to the present worth of the amortization of the investment plus the return upon the unamortized portion of the investment. This principle can be complied with, however, by the consistent application of any method of amortization whatever, regardless of its relation or lack of relation to depreciation.

Confusion has also been caused by the controversies and contradictions that have grown up around the meaning of "fair value" in regulation of public utilities, and the legal measure of depreciation in determining "fair value." The Courts have performed a valuable service in emphasizing the reasonableness of the correspondence of such legal measure with the facts:[22]

> "The testimony of competent valuation engineers who examined the property and made estimates of its condition is to be preferred to mere calculations based on averages and assumed probabilities."

Further evidence is given in the following:[23]

> "In the light of the evidence as to the expenditures for current maintenance and the proved condition of the property—in the face of the disparity between the actual extent of depreciation, as ascertained according to the comprehensive standards used by the company's witnesses, and the amount of the depreciation reserve—it cannot be said that the reserve merely represents the consumption of capital in the service rendered."

It is proposed now to discuss briefly each of the principal recognized causes of depreciation that have been enumerated as follows: (1) Physical deterioration; (2) obsoleteness; (3) inadequacy and change in use or in demand; and (4) requirement of public authority.

Physical Deterioration

Where property is used up and disappears progressively with use as, for example, the lead in a pencil or the material in a grindstone, such use is analogous to the consumption of such supplies as fuel taken from a coal pile. Such consumption, of course, can be measured in simple units of length, volume, or weight.

When the use of property can be isolated for study, it may be possible to measure the progress of deterioration as a function of such use. Wood poles, for example, have a single use—that of sustaining over-head conductors by reaction to vertical compression, on the one hand, and of supporting unbalanced span loads and lateral wind loads through resistance to bending, on the other. It is suggested that deterioration through fiber rot in such a case may reasonably be measured in terms of decline in compression and bending strength at standard fiber stresses.

---

[22] McArdle v. Indianapolis Water Co., 272 U. S. 400 (1926).

[23] Lindheimer v. Illinois Bell Telephone Co., 292 U. S. 151 (1934).

The foregoing examples are cases in which simple objective measurements of the effects of deterioration appear reasonably applicable. In many types of cases, however, the relation of deterioration to objective measurements is less obvious. Thus, when a steam boiler is new it can operate under a definite pressure limitation as prescribed by the A.S.M.E. standards and boiler insurance codes. Furthermore, the tubes, shells, and headers have definite thicknesses of sound metal designed to support the anticipated stresses with reasonable factors of safety. As deterioration occurs, the thickness of sound metal is reduced. De-rating of boilers by insurance inspectors supplies an additional objective measure of the extent of deterioration.

Similarly, changes in the dielectric strength of insulation and in other physical and chemical characteristics occur in the windings of generator coils as a result of use and of changes in temperature and dielectric stress. Extensive measurements of some of these characteristics have been made by manufacturers and by engineering committees in an effort to describe them.

In these and in similar cases, however, it would be impossible, in the present state of knowledge, to secure agreement upon any standard series of objective measurements that would be generally accepted as measuring the extent of deterioration. Engineering estimates of conditions reflecting the extent of deterioration in such cases, therefore, are customarily stated as representing the judgment of the engineer as to the point where the deteriorated condition of the property in question would fall on a scale between 100%, representing condition new, and 0%, representing a condition requiring removal, if all degrees of deterioration were arranged in order of magnitude.

Such a judgment, of course, is in a measure subjective. It has been the experience of the writer, however, that such judgments of a number of competent observers of similar training and experience with respect to an identical condition tend to be reasonably consistent and to group themselves around a mean without excessive deviations.

It may be that in judging condition or extent of deterioration, engineers are in somewhat the same situation as men were when they attempted to convey to one another their relative sensations on touching similar objects at different temperature levels before it was known that temperature was proportional to molecular velocity or that a convenient scale for the measurement of temperature could be established by measuring the length of a column of mercury in a glass tube.

The time may come when the processes of deterioration will be sufficiently understood so that several objective measurements may be recognized as completely describing all the types of physical deterioration that have occurred in an item of property and may be synthesized into a determination of condition that is related as closely to objective observations as the unused length of the lead in the pencil, the remaining stone in a grindstone, the weight of fuel in a coal pile, or the remaining fiber strength of a wood pole.

The writer believes that progress in this direction depends upon engineering study, and proposes that civil engineers invite the co-operation of engineers in other branches of the profession specializing in the design, construction, and operation of power plants in undertaking to devise more complete objective standards for the measurement of the effects of deterioration of power plant structures and equipment, and of suggesting improved methods of arriving at sound engineering judgments and valid statistical inferences in the light of such objective standards as are already available.

OBSOLETENESS

Attention is called to the use of the word, "obsoleteness," instead of "obsolescence" as included in the title of this paper, in deference to the use of the latter term in the designation of the Sub-Committee of the Power Division, of which the writer is Chairman. The use of "obsolescence," derived from the inceptive Latin verb ending in "-sco," is misleading, since such verbs describe verbal actions commencing and progressing continuously with the passage of time. "Obsoleteness," derived from a past participle describing a completed verbal action, seems more suitable for describing a condition existing at a particular time, especially when it is intended to refer to a condition resulting from a cause which is discontinuous in time and which becomes effective upon occurrence of specific events, such as the development of new inventions or other steps in the progress of the arts.

It is suggested that the decline in the economic value of existing equipment, resulting from the development of improved equipment, which can be operated at a saving, may reasonably be used as a measure of obsoleteness. Economic value is defined as the sum of the present worths of the expected returns, where such returns are equal to the total revenues less all operating expenses (exclusive of provision for depreciation or amortization).

Progress in the arts tends to affect competitive enterprises by attracting into the field lower cost producers, with resultant lowering of prices, elimination of marginal producers, and decline of the profits and economic values of remaining enterprises using obsolete facilities.

With a relatively inelastic demand, such decline of economic value may be stated as the total of the cost of the old equipment plus the sum of the present worths of its operating expenses (exclusive of depreciation or amortization) over a reasonable period of time, minus the corresponding total for the most modern available improved equipment. The ratio of decline is this difference divided by the cost of the old equipment.

Algebraically, the percentage effect of such obsoleteness may be stated as follows:

$$D_o = 100 \frac{C - [C_e - \sum_{o}^{n} W_p (O - O_e)]}{C} \ldots\ldots\ldots\ldots\ldots (3)$$

in which D_o = percentage depreciation due to obsoleteness; C = cost of existing equipment; O = annual operating expenses associated with existing equipment (exclusive of depreciation); C_e = cost of the most economical modern substitute equipment; O_e = annual operating expenses associated with the most economical modern substitute equipment (exclusive of depreciation); and, $\sum_{o}^{n} W_p$ = sum of the present worths of an annual sum over a reasonable period of n years.

In some instances, improved equipment results in greater safety, greater reliability, or improved quality of product, rather than in realizable savings in operating and maintenance expense, and in such cases the measurement of obsoleteness appears less simple and has the subjective character of engineering judgments to which reference has been made in connection with estimates of some forms of physical deterioration, and the judgment is expressed as a percentage on a scale between 100% and zero. In this case, also, there would seem to be opportunity for the development of objective measurement by engineering study, and for progress toward an objective basis for judgment.

Inadequacy and Change in Use or in Demand

As in the case of obsoleteness, these causes of depreciation become effective as a result of specific events, such as addition of new load, loss of load, change in market, or change in method of operation. Inadequacy is rarely encountered in well managed profitable enterprises, for the reason that in such cases facilities are promptly increased to take advantage of opportunities for profitable employment of capital. Excess capacity due to decline in market or change in methods of operation, however, is not uncommon and there is opportunity for clarification of its meaning and development of improved methods of measuring its effects. The analogy of decline in price, to the extent of savings in cost of production that could be accomplished by a producer, with no more than adequate equipment, appears reasonable as a basis of measurement and on this basis the percentage depreciation due to change in demand or in use is, as before:

$$D_u = 100 \frac{C - [C_a - \sum_{o}^{n} W_p \, (O - O_a)]}{C} \quad \ldots\ldots\ldots\ldots\ldots (4)$$

in which D_u = percentage depreciation due to change in use; and C_a and O_a are the cost and the annual cost of operation of equipment of no more than adequate capacity.

Requirement of Public Authority

The effects of this cause of depreciation are rarely found in property in service, because compliance with such requirements is ordinarily compulsory, and retirement and replacement take place at the effective date of such requirement. Where property is maintained in contravention of legal requirement by competent public authority, either the property right in such property has in effect been destroyed, and depreciation due to this cause should be considered complete; or a liability is imposed upon the owner of the property, the amount of which may be taken as a measure of depreciation due to this cause.

Annual Depreciation Expense

If the existing depreciation in the property is the sum of the effects of the several causes of depreciation that have been discussed herein, the annual depreciation expense should be the sum needed to make the reserve for depreciation representative of existing depreciation at the beginning and at the end of each year. If it were practicable to make a depreciation study as of January 1 of each year and determine the existing depreciation, it would be possible to compute the reserve requirements at such dates. Then, the annual depreciation expense would be the difference between the required reserves at the beginning and at the end of the year plus the debits to the reserve during the year. The debits to the reserve during the year are the net retirement losses, which are equal to the difference between the sum of the cost of the property retired plus the costs of dismantling and the salvage recovered.

Of course, a complete new depreciation study as of January 1 of each year cannot be made on account of the magnitude of the task and the time required to make the determination of existing depreciation. However, it is possible to approximate, within narrow limits, the probable change in the amount of existing depreciation during a year, and thus to approximate the amount of annual depreciation expense.

The difficulty of determining the annual depreciation expense arises from the discontinuous relation of some of the causes of depreciation to time. The result of this difficulty has been that depreciation due to all causes has generally been treated either as if all these causes became effective directly and solely in proportion to the passage of time, and as if depreciation were identical with amortization of investment by a straight line or a compound interest formula; or as if none of these causes was effective in proportion to the passage of time, and as if depreciation losses occurred only at the time of retirement of property.

It is suggested that a rational engineering approach to the problem would be to recognize that the effects of some causes of depreciation on some property do proceed in a simple functional relation to time and that others do not; and to attempt to formulate a plan for computing annual depreciation which will more nearly correspond with facts than either of the erroneous treatments to which reference has been made.

The writer does not minimize the difficulties of such an approach. He believes, however, that engineering study offers promise of progress in the direction indicated which is well worth the effort of attempting to overcome the difficulties that lie in the way. With this in mind he proposes to describe briefly a procedure which he has developed and used in studies made under his direction.

Of all the causes of depreciation, physical deterioration comes the nearest, and in a greater proportion of cases, to progressing approximately in proportion to the passage of time, whereas obsoleteness, inadequacy, change in use or in demand, and requirement of public authority occur irregularly, and often at the time of the retirement of a property. Admitting freely the inaccuracy of the assumption and pending the development of more complete knowledge of the relation between incidence of the causes of depreciation with respect to the particular property and the passage of time, it is suggested that a helpful guide to the determination of annual depreciation expense in many cases will be found in a computation based upon the assumption that deterioration does progress directly in proportion to the passage of time, and that the other causes of depreciation become effective at the time of retirement and can be provided for as retirement losses.

To make such a computation it must be recognized that the physical condition determined by an engineer, in the manner previously described, is the result of two offsetting influences: (1) Deterioration, which acts to lower the condition of the property; and (2) the replacement of parts through maintenance, which tends to restore the condition of the property.

The physical condition of the property as found is the net result of the effect of these opposing influences during the history of the property. Every dollar spent on maintenance, however, does not improve the condition of the property. Some maintenance expenditures tend only to prevent deterioration and others affect only the location or arrangement of property. The cost of replacing parts on maintenance, also, because of its piecemeal character, may be substantially greater than the cost of the parts replaced as portions of the cost of property used in operations.

If it is assumed: (1) That a constant proportion of maintenance expenditures has been effective in restoring deterioration; (2) that maintenance expenditures have been spread evenly over the property whose condition has been determined; and (3) that parts replaced on maintenance tend to deteriorate at the same average rate as all the property whose condition has been determined, then it is suggested that the relation of these several factors may be expressed by the equation:

$$K_n = 100 \left[1.00 - X\, Y_n + \frac{b_n}{B_n} (I)\,(1.00 - X\, y_n) \right] \ldots\ldots\ldots (5)$$

in which K_n = percentage condition resulting from physical deterioration; X = average annual rate of deterioration in the past; Y_n = weighted average age in years of dollars representing the property; $\frac{b_n}{B_n}$ = ratio of cumulated maintenance expenditures (b_n) to fixed capital balance, representing the property (B_n); I = ratio of maintenance expenditures effective in restoration of condition; y_n = weighted average age in years of cumulated maintenance expenditures; and n = subscript indicating year, January 1 of which is the basis of the study.

Equation (5) may be solved for X, which is the average rate of deterioration independent of the offsetting effects of maintenance. The reciprocal of X may be considered as an average indicated useful physical life, which the property would live if the constant rate of deterioration continued from 100% to 0% condition, and if it were retired solely because of physical deterioration.

With the same assumptions as before, and with amounts budgeted for additions, retirements, and maintenance expenditures for an ensuing year following the date for which existing depreciation has been determined, the annual depreciation expense, D_a, may be stated as follows:

$$D_a = [B_{n+1}\,(1.00 - K_{n+1}\, M_n) - B_n\,(1.00 - K_n\, M_n)] + R_n \ldots . (6)$$

in which M_n = the net percentage effect of all causes of depreciation other than deterioration; R_n = the estimated net retirement loss in the ensuing year; and K_{n+1} is expressed by Equation (5) for $n = n + 1$ (the subscript,

$n + 1$, indicates merely that the figures to which they are applicable are those of a year later than n).

The writer has found this formulation useful (although it is inchoate), in estimating the costs required to be budgeted for depreciation expense during a year following a determination of existing depreciation. Where depreciation reserves have been established in accounts that are the same proportion of the book cost of depreciable property as the percentage depreciation at the beginning of the year determined by engineering study in the manner described, this procedure will tend to preserve such correspondence between reserves and actual depreciation at the end of the ensuing year.

The procedure, of course, is capable of indefinite refinement, as information and a better understanding of the facts of the particular case become available. If there is ground for anticipating that deterioration of some part of the property will not proceed in proportion to the progress of time, correction may be made on this account. If the causes of obsoleteness, inadequacy, or change in use or in demand are known to be in operation in a manner that will result in additional depreciation during the ensuing year, due to these causes, without justifying retirement, a proportionate allowance may be made for these factors. It may be desirable in any case to increase the estimated requirement for depreciation expense by a percentage for contingencies to allow for the obvious limitations on the accuracy of the procedure. If such a procedure should be followed for a number of years it would probably be desirable, possibly at intervals of five to ten years, to check the correspondence between the resultant reserves and the actual depreciation of the property by a re-examination of its condition and by new engineering studies of obsoleteness and of the effects of change in demand or in use.

It does not seem worth while, at this time, to labor the point, or to attempt to develop, in any more detail, the solution of the practical problems that will be encountered in the application of this procedure. The purpose is to emphasize the opportunity for a contribution by the Engineering Profession to a rational solution of this problem which it is believed will have application to competitive industry, to public utilities, and to the determination of the cost of power developed by public projects, to which it is now proposed to make brief reference.

COMPETITIVE INDUSTRY

In competitive industry the prices of products tend to be determined by equating utility to the marginal consumer to cost to the marginal producer. Profit is the difference between price, as so determined in the market, and cost of production. Neither price nor profit has any necessary relation to the investment in fixed facilities of the particular enterprise under consideration; and the value of the enterprise is the present worth of its prospective earnings including profit and recoupment of investment at such time and in such manner as the profitable operation of the enterprise in the competitive market may make possible.

The policy of management, however, as to amortization of investment may be based on considerations other than the occurrence of actual depreciation and retirement losses. Thus, if a uniform product is manufactured and sold, it may be desirable that the entire cost of amortization of investment—or possibly that all costs—shall be spread over the total number of units of the product, regardless of the time when, and the rates at which, such costs or losses are actually incurred. On the other hand, a more limited equalization of the effect of depreciation on cost of production in accordance with some other plan may be desirable because of some other special consideration. It has seemed to the writer that it is for this reason that depreciation and amortization of investment have been so generally considered as identical in accounting practice.

It is suggested, however, that knowledge of the actual time and rate of occurrence of losses due to depreciation, based upon competent engineering study, will be helpful to management even when amortization policies are not controlled by depreciation. The tendency to extend governmental supervision over financial and accounting practices in connection with the issue of securities, moreover (as illustrated by developments under the Security and Exchange Acts), suggests the possibility that even in competitive industry a closer correspondence between such practices and the actual facts of depreciation may be necessary or desirable at some time in the future.

Public Utilities

In the public utility industry the situation seems to be quite different. The principle has been established that public utility rates are to be based upon allowance of gross revenues from sales of service equal to operating expense, plus annual depreciation, plus a reasonable return on the fair value of the property used and useful in the public service. Fair value, as prescribed by the Courts, must be based upon consideration of reproduction cost less depreciation, prudent investment less depreciation, and other pertinent measures of value. The tendency of the Courts, in prescribing these general requirements, has been to insist that depreciation deducted in determining fair value shall be "actual depreciation," and that there must be a reasonable correspondence between such "actual depreciation" and the reserves resulting from the annual depreciation included in operating expense.

The freedom of competitive industry to amortize investment in any manner suggested by the special conditions of the industry is limited by the definite requirement that depreciation charges and reserves shall correspond as closely as possible with the facts as to depreciation losses and the condition of the property from time to time, taking into account all the effective causes of depreciation.

The tendency toward clarification of this requirement has received a marked impetus in the two years, 1936–1937, through adoption by various Federal and State regulatory commissions of new classifications of accounts requiring (to quote the language of the classification of the Federal Power Commission, for example) that "each utility shall record as at the end of each month the estimated amount of depreciation accrued during that month on depreciable electric plant."

The method of approach herein outlined complies with these special requirements which are applicable to the public utility industry. Even the suggested methods of measuring the effects of obsoleteness and excess capacity due to change in demand or in use, derived from the analogy of the economic effect of such changes on price and economic value in the competitive field, seem to be directly applicable. The regulation of semi-monopolistic public utility enterprises constitutes, in effect, the substitution of an artificial simulation of competitive conditions to make up for the lack of the influence of free competition on prices.

The references previously made to opportunities for refinement of methods of calculation, with increasing knowledge of facts and their relations, are especially applicable in the present case. Some equalization of requirements for annual depreciation expense by averaging over reasonable periods of years may also be desirable. In special cases, as where the property of a public utility consists of a single long-lived unit, like a hydro-electric dam, it may even be desirable, as a matter of public policy, to equalize such costs by a compound interest formula over a long period of years.

However, even such departures of amortization provision from depreciation, if desirable, cannot be made intelligently, and cannot avoid that unreasonable disparity between existing depreciation and reserves which has been condemned by the Courts, unless the facts are fully understood on the basis of proper engineering investigation and analysis. Such engineering investigation and analysis may well provide a more generally accepted basis of determining amortization based upon average depreciation experience for the purpose of making economic comparisons of different types of design and of the relative costs of steam and of hydro-electric power. The importance of such development is illustrated by the widespread discussion that followed the publication in November, 1937, of the report of the Power Authority of the State of New York on "Government Hydro *v.* Private Steam Power." In this report it was shown that the average fixed charges of four modern base-load steam-generating stations, furnishing power to distributing companies under contract, included depreciation varying from 1.90% to 3.25 per cent. The Authority adopted 2.0% as a reasonable comparative allowance for depreciation and renewals on both public and private water power plants, and 3.0%, based on sinking-fund accrual at 7% interest, as a reasonable comparative allowance for private steam generating stations.[24]

COST OF POWER PRODUCED BY GOVERNMENTAL PROJECTS

As in the case of competitive industry, the amortization of investments in public projects of any character may be controlled by considerations of policy unrelated to the occurrence of depreciation in the property representing such investments. It is not intended to suggest that it is a function of this Society, or of any other engineering organization, as such, to discuss such governmental policies. It is suggested, however, that, as in the case of competitive industry, knowledge of the engineering facts relating to the occurrence of depreciation in such property will be helpful to all those concerned in such policies, including governmental officers, tax-payers, and voters; and it is obvious that if helpful comparisons are to be made of costs of power produced by governmental projects, and of those produced by private agencies, it will be helpful to include costs of depreciation in both on a strictly comparable basis.

---

[24] H. R. Committee on Rivers and Harbors, Doc. No. 52, 75th Cong., 2d Session, pp. 26, 37, 38.

CONCLUSION

The purpose of the writer in presenting this discussion of depreciation has been primarily to emphasize the engineering aspects of the problem, to which he believes sufficient consideration has not been given in the past, and to suggest that an opportunity be afforded the Engineering Profession to clarify this highly controversial subject by discussion of its engineering aspects. He ventures to express the hope that civil engineers will take the lead in this engineering activity, and will invite the co-operation of engineers in all branches of the profession in carrying forward a program which, he is convinced, can be made of great value, both to the profession and to the public.

RECAPITULATION

BY W. F. UHL,[25] M. AM. SOC. C. E.

SYNOPSIS

The final paper of a Symposium presumably is useful if it summarizes the salient facts revealed in each paper and points out divergencies of opinion where they may be found. It can also properly present conclusions and some of the economic aspects of the subject-matter.

It was thought best to confine the Second Symposium on Power Costs to generation only, in order that the issue might not be confused. Later, it is hoped that the more complex problem of cost of transmission and distribution may form the subject of a Third Symposium.

A study of the papers comprising this Symposium indicates that the cost of generating power is indeed a variable quantity. This is a well-known fact which it should be unnecessary to discuss at length, but many recent statements emanating from sources that should be well informed indicate that the belief is abroad that power should be produced at a fixed price or that a "yardstick" of some kind can be set up to measure the cost of power.

It is clear that, considering all the variables, it must be a mere accident if the cost of power generated in any two or more stations is the same. No attempt has been made in this paper to summarize facts and conclusions separately.

ELEMENTS OF POWER COST

Recent papers relating to the cost of power indicate that some of the fundamental principles involved are sometimes overlooked. These principles are well established. An honest difference of opinion can exist regarding their application but they may not be disregarded except as a convenient means of promoting unsound projects. Engineers cannot properly become promoters unless they acknowledge such activities.

The total cost of generating power consists of fixed charges and operating costs. These terms are well understood. Fixed charges may vary between wide limits, depending on cost of money (interest), depreciation and obsolescence experience, taxes, and possibly some other minor items. Operating costs can be more readily determined, but where costs are to be determined for the future, there can be honest disagreement on such items as maintenance, fuel, labor, etc.

With steam power plants the major uncertainty is the variable cost of fuel and the increasing cost of attendance. During recent years the rapid advance in the art of steam power generation makes it difficult to estimate depreciation and obsolescence. With hydro-plants the major uncertainty is the available stream flow. This is highly speculative in most cases and, at best, can only be based on records covering past experience where such records are available. Extreme drought and flood conditions are seldom known.

---

[25] Hydr. Engr., Chas. T. Main, Inc., Boston, Mass.

Quality of power as reflected by outages, voltage, and speed control, should receive consideration. Comparative reliability of operation must also be considered and the importance of reliability under certain conditions stressed.

Engineers with experience in the power field are thoroughly familiar with all items that must be considered in arriving at power costs, but very often there is a marked difference of opinion regarding the total fixed charges to be included in such costs. The principal items usually included in fixed charges are: (1) Cost of money; (2) depreciation and obsolescence; (3) taxes; and (4) insurance.

(1).—Cost of Money, or as More Commonly Referred to, Interest.—This item can vary within wide limits, depending principally upon financial conditions, the credit of the borrower, the popularity of the business, the hazards involved, and other matters. Some municipalities and boards, set up by legislative enactment for special purposes, have borrowed money for power plants at interest rates as low as 3% to 3.5%, whereas the average rate of interest for private concerns has generally varied between 6% and 8%, although a part of their money might be borrowed at rates as low as 4% to 6 per cent.

(2).—Depreciation and Obsolescence.—These items depend largely on the economic life of a plant which, in turn, depends principally on the design, materials, workmanship, and quality, in the construction and equipment, the extent to which the plant is used, its operation and maintenance, and the state of the art. It can be readily seen that there can be a wide difference of honest opinion regarding such matters.

Present experience indicates that the economic life of a steam plant is probably from 20 to 35 yr, whereas a well-designed and constructed hydro-plant may have an economic life of from 40 to 50 yr, or longer. In other words, the average rate of depreciation may be as high as 5% for a steam plant and as low as 2% for a hydro-plant.

Where the investment in plant is amortized by a sinking fund, it is necessary to establish the term of the useful life of the plant and the probable rate of return on the fund set aside, both of which items are speculative.

The prevailing practice of superposing high-pressure steam turbine units on old low-pressure plants which may have already been operated 10 to 15 yr, or more, complicates the depreciation problem in such cases. Overhauling the older units may be justified economically where they act as the low-pressure part of the new plant, since they now have an additional useful life of a more or less indeterminate character.

The future advance in the art of steam-power generation alone can determine whether the new superposed unit will have a useful life fixed by the remaining life of the older units or whether the life of the older units will be fixed by the useful life of the new high-pressure unit. The problem is not unlike that which presents itself when old hydro-plants are redeveloped and many structures are found suitable for continued use.

(*3*).—*Taxes.*—The principal taxes to be considered are property taxes to City, Township, County, and State. A portion of the owner's Corporation Franchise, State, and Federal income taxes may also be properly chargeable to power generation.

Property taxes on hydro-plants are often very much less in the country than the property taxes on steam plants which are generally situated near load centers. Social security and unemployment assessments must also be included. Taxes may vary from 1.5% to 4%, or more.

(*4*).—*Insurance.*—Insurance is a relatively minor item but is becoming more important as liability insurance has been gradually increasing. Fire, electrical, boiler, and fly-wheel insurance, as well as insurance against damage by the elements, are often carried. The amount of this insurance depends largely upon individual judgment. Generally, the insurance carried on hydro-plants and their equipment is materially less than that carried in connection with steam plants. Insurance usually varies from 0.25% to 0.75 per cent.

A summary of the foregoing items, constituting the annual fixed charges on power plants, indicates that the total may be as low as about 7%, or as high as about 18% of the capital cost. Fixed charges on hydro-plants usually vary from 8% to 11%, and on steam plants from 12% to 15 per cent.

The principal items usually included with operating cost are fuel, water, labor, maintenance, oil and supplies, repairs, superintendence, accidents and damages, general and miscellaneous expense, management, legal expense, etc.

Operating costs for hydro-plants are relatively small and do not vary much with the output of the plant. For steam plants, operating costs are relatively high and vary greatly, depending largely on the capacity factor of the plant, and for the most part on the cost of fuel. On the other hand, the total annual fixed costs for hydro-plants generally are higher than for steam plants, due to greater capital cost per unit of dependable hydro-plant capacity.

Where more than one plant carries the load of an inter-connected system, the average cost of generation must be considered, as well as the generating cost of some particular plant which may be operated at a high load and capacity factor. Money tied up in coal storage and working capital may also be considered a charge against the cost of generating power.

HEAT-GENERATED ENERGY

Published cost records and individual experience show that the cost of steam power plants varies widely. Conditions under which they are built, their location, reserve capacity, load conditions, nature of service to be rendered, and other matters, have a marked effect on the capital cost. In studying the capital cost of steam plants, it is important that item for item be compared so that conclusions will not be misleading.

Data published on the cost of plants do not always state what is included. Besides the usual itemized account, including the plant rating, the number, size, and type of generating and boiler units, steam pressure and temperature, type of service, fuel used, number of outgoing lines, voltage of lines, condensing water conditions, etc., it is important to know something about land, buildings, foundations, water tunnels, coal and ash-handling equipment, or equipment for servicing other fuel where used, boiler and turbine-room auxiliaries, switching arrangements, outgoing feeder lines, step-up sub-station equipment, etc. The extent of reserve capacity should also be stated.

Published costs show the following: One list of 150 plants built between 1882 and 1936 is stated to show an average cost of $100 per kw.[26] Another list of 80 plants built since 1920 shows an average cost of $108 per kw. Five of these plants cost more than $150, and four less than $70 per kw.[27]

Another list of sixteen plants built between 1924 and 1937 shows a range in cost, including step-up sub-station equipment, from $101 to $180 per kw, the average being $139 per kw.[28] Still another list of sixteen plants built since 1927 shows a range of cost from $82.50 to $145.00 per kw, with an average cost of $114 per kw.[29] These costs do not include any reserve capacity. Adequate reserve capacity may add from 20% to 40% to the cost of dependable generating capacity.

The records of cost of steam plants indicate that the size of the plant has little if any effect on the unit cost and the same is true of steam pressure and temperature. However, in general, it may be stated that the total power cost tends to decrease as the size of plant is increased.

Station service requirements for steam power plants are from 5% to 8% of the installed capacity. This service includes pumping, fuel handling and preparation, fans and other auxiliaries, and lighting. The power requirements for station service may be supplied in different ways, depending on the heat cycle. The necessary power may be supplied by the main unit and delivered through house-service transformers; it may be produced by house-service generators; or, the auxiliary equipment may be steam driven.

When steam power plants form a part of an inter-connected power system, a portion or all of their output may be transmitted over high-tension lines, thus requiring step-up sub-stations. Many of the large new steam power plants are some distance from the larger load centers and in such cases the entire output may require transmission at higher than generator voltages. In making comparisons between cost of plants, these questions must receive consideration.

The cost of the unit output of the steam power plant, assuming that the fixed charges are agreed upon, depends principally on the capacity and load factors and the cost of fuel. It will be found that the unit cost of generating steam power will vary just as widely as the capital cost.

Particular attention should be called to the difference in cost of steam power from plants designed with full auxiliaries and reserve capacity and those designed for less reliable service. Fixed charges per kilowatt-hour of output from modern steam power plants costing about $100 per kw and using 12% fixed charges, may vary from 0.17 to 0.7 cent, or more, depending on the capacity factor, which may vary from 80% to 20%, or less. Fuel costs per kilowatt-hour of net output will vary from about 0.17 cent at 80% capacity factor to 0.3 cent at 20% capacity factor, with fuel costing 15 cents per million Btu and with a 1-in. condenser back-pressure.

---

[26] "Progress in Generation of Energy by Heat Engines" (First Symposium on Power Costs), by Geo. A. Orrok, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., December, 1937, p. 1888.

[27] From records of the Federal Power Comm.

[28] *Electrical World*, October 27, 1928.

[29] *Loc. cit.*, November 23, 1935.

Total costs per kilowatt-hour composed of fixed charges, operation, maintenance, and fuel, will vary from about 0.4 cent at 80% capacity factor to 1.1 cents at 20% capacity factor for plants costing $100 per kw, with fixed charges at 12%, and fuel costing 15 cents per million Btu.

These costs are for a net output on low-tension terminals of large modern plants of 150 000 to 250 000-kw capacity with steam pressures from 400 lb to 1 250 lb, and temperatures from 650° F to 925° F, and without provisions for reserve capacity. General over-head expense will add from 10% to 25% to the foregoing unit costs.

Diesel and gas engine installations for the generation of electric energy are mostly made with relatively small units and for comparatively small plants. The total installation of such plants is also small compared with the water power and steam power installations.

Based on an investment cost of $135 per kw, 13% fixed charges, and 5 cents per gal for fuel oil, the total generating costs per kilowatt-hour net output from Diesel engine plants (includingg eneral over-head expense) will vary from 2 to 2.5 cents for operation at 20% capacity factor, to about 0.8 cent for operation at 80% capacity factor. A suitable reserve capacity will add somewhat to these costs.

Hydro-Generated Energy

Comparisons between capital costs of hydro-plants are even more difficult to make than comparisons between costs of steam plants, since the natural conditions to which hydro-plants must be suited are more variable and generally more difficult than the steam-plant locations which are subject to some choice. The installed capacity of hydro-plants with relation to the available stream flow also varies widely, depending largely on the load to be served and the available pondage and storage.

The cost of economic hydro-electric developments varies from $100 to $300 per kw of installed capacity. The cost of the greatest number for which data are available varies from $150 to $200 per kw. Higher costs than $300 per kw may sometimes be justified under special load conditions. In general, unit cost decreases as head and size of plant increase.

One of the principal difficulties in establishing the true capital cost of hydro-plants from which the full output cannot be used immediately, is the added capital cost due to fixed cost on the unused part of the plant. Generating units can be added from time to time, but the major cost is in the water rights and structures other than the power-house.

A comparison of hydro-plant costs based on the installed capacity is almost meaningless since plants are found which can operate to capacity only 3% to 5% of the time, due to stream flow limitations, whereas some plants can operate to capacity from 75% to 100% of the time on the available stream flow.

The earlier hydro-plants were developed for private industrial use at a time when the art of steam power generation was relatively uneconomical. As the power load of the industries increased and continuity of power supply became more important with the advance of the industrial age, steam power was usually installed to supplement the water power during the seasons of low stream flow. Many of these industrial hydro-plants have been redeveloped in recent years, and generation and distribution of output have been changed from mechanical to electrical. Some of the old structures built for the original hydro-plants, such as dams, canals, conduits, and tail-races (and, in some cases, even the power-house), are utilized to a greater or less extent in the redevelopment.

The cost of such redevelopment generally varies from $75 to $100 per kw of installed capacity. The cost of operation and maintenance of these industrial plants is very low. Many are operated without continuous attendance. Pumped-storage hydro-plants can sometimes be built to carry the peak load of a system and thus improve the load factor on the remainder of the plants in the system. They may also be relied on for emergency reserve capacity. For some reason this type of plant has not been adopted extensively in the United States, but quite a number of them have been built in Europe. Natural conditions which permit construction of such plants at reasonable cost and where their output does not require excessive transmission costs, are factors that have an important bearing on the economic advantage which such plants might have over other peak capacity.

The cost of hydro-generated energy, assuming agreement on fixed charges, may be readily determined if the usable output is known, since costs other than fixed charges are nominal. Operation and maintenance costs per kilowatt-hour of output depend largely on the size of the plant and somewhat on its design and construction. For plants of from 5 000 kw to 10 000 kw capacity, these costs may vary from 0.1 to 0.05 cent per kw-hr and for large plants they may be as low as 0.02 to 0.01 cent per kw-hr. Total generating costs consisting of fixed charges computed at 10% and operation and maintenance vary from 0.25 cent to 3 cents and more per kw-hr. Although, in general, the cost per kilowatt-hour tends to lessen as the head and the size of the plant increase, the effect of capacity factor is more predominant.

STEAM AND WATER POWER COMBINED

The earlier hydro-plants were usually developed as a main source of power. This is true with respect to both industrial and public utility hydro-plants. As the loads increased it was generally found more economical to install a supplementary steam plant to be operated during low-water seasons rather than a second water-power plant. Such supplementary steam plants were built at low cost without much regard for economy of operation since they were not in use much of the time.

The utilization factor of most hydro-plants operated by themselves is generally very low unless a portion of their output is sold as dump power. In some cases in the West and in many places in Canada, hydro-plants always did, and still do, carry the entire power load of very large systems. It is true that occasionally during extreme droughts the output must be curtailed, but usually arrangements are made to drop some of the low-price load which is taken on with the understanding that this can be done.

Water power and steam power are not often economically competitive, but ordinarily are complementary if used to best advantage. Under modern conditions, water power finds its greatest economic use where it supplements steam power, since it is found that in many cases where sufficient flow and pondage are available, incremental hydro-capacity costs less than incremental steam plant capacity. It also has certain advantages as reserve capacity since hydro-plant units can be started and their output placed on the outgoing lines in a few minutes whereas steam units must be kept hot and revolving for some time before they can be put under load. Hydro-capacity can also be used for power-factor correction at small cost.

Hydro-electric energy output should cost no more than the fuel cost of an equal amount of steam-generated energy if credit is allowed for that portion of the hydro-plant capacity which is capable of carrying peak loads or which acts as reserve capacity. Usually, hydro-plants are not developed unless they show some margin of economy over steam.

Small water-power plants near load centers or near the ends of transmission or distribution systems often have a value which they would not have if they were situated at a distance requiring the transmission of the energy generated to a distant market. If they were near a load which would otherwise be supplied over a transmission line from a distant power plant, there is a saving in transmission losses and there are certain advantages due to possible voltage control and power factor correction. If pondage is available, such plants also have a capacity value. There is also the additional advantage that during transmission difficulties at least a part of the local and near-by load can be supplied from such a plant.

It is often claimed that Niagara Falls furnishes a water power that is sufficient in itself and does not require a supplementary source of power, since the stream flow is such that a practically constant output of water power is available. However, even Niagara power cannot be fully utilized, except as a part of a large system having a substantial amount of steam power, since a load requiring a constant output has not yet been discovered.

Niagara, "tied in" with steam power, can carry a large base load, and thus can be utilized quite fully; whereas, if operated by itself, there would be many periods when much of the available water would be wasted due to lack of demand. Ultimately, every water power can be more fully utilized if operated in conjunction with heat energy plants.

Economic Importance of Cost of Power

Available statistics indicate that in 1936 the total stationary power plant installations in the United States amounted to about 75 000 000 hp, divided as follows:

Steam plants	56 684 000
Hydro-plants	16 075 000
Oil and gas engine plants	2 000 000
Total	74 759 000

An average cost of $100 per hp (about $135 per kw) would make the total investment in stationary power plants about $7 500 000 000 as of 1936. The actual investment is probably much larger, and the annual investment in such plants has become one of the major items of national business.

If the cost of power is compared with the cost of other commodities for which there is a similar universal demand, it would appear that the unit cost of its generation is unimportant, particularly since such cost is only a small part of the cost of delivering it to the ultimate consumer, as in the case of public utility service.

The total power generated by the public utilities alone, during 1937, was about 125 billion kw-hr. A difference of 1 mill per kw-hr represents a sum of $125 000 000. This indicates that power use in the United States has reached such proportions that small savings in generation are extremely important. However, it is much more important that an abundant and reliable supply of power be available than a source of cheap power which may be unreliable.

By far the greatest power capacity in this country is in the automotive field, probably about 1 billion hp. The power produced by this automotive equipment can certainly not be classed as cheap power, but automobile and airplane engines to-day furnish a supply of reliable power, a condition one would scarcely care to change if reducing the cost of this power resulted in less reliability.

Cost comparisons have often been made between power generated in different parts of the country and between steam and water power. Assuming that all other factors affecting cost of power are considered, such comparisons may be very misleading unless a careful analysis is made of the quality of the power supply. Quality embraces such matters as continuity of supply throughout the seasons, outages of short duration, speed and voltage control, etc. In making power-cost comparisons, the quality of the power supply must be given due consideration.

Power cost is a relatively unimportant item to many industries but the continuity and quality of power supply may be extremely important when profitable business is being processed. Reduced production or spoiled materials are more important than cost of power to most industries.

The ratio of power cost to the total cost of production is small in most industries. It is less than 10% of the total cost of manufacturing in all except perhaps ten or a dozen industries. In many industries the cost of power is less than 1% of the cost of manufacturing.

The ratio of the power cost to the total value of products for 100 different industries averages about 2.64 per cent.[30] The following information on the cost of power was reported by one newspaper:[31]

"A shade over 10 per cent of the total cost of manufacturing our paper goes to the Ontario Hydro-electric Commission at Niagara Falls for purchased power, and a shade less than 9 per cent covers the cost of making the paper and its delivery in Chicago. * * * If our mill was fully equipped with modern machinery, the cost of power could be brought down to about 6.6 per cent. * * * The ink factory power cost is 2.1 per cent of the cost of manufacturing. * * *

---

[30] *Magazine of Wall Street*, 1926, Vol. 38, p. 568.

[31] *Public Service Magazine*, Vol. 53, No. 4, October, 1932, pp. 101–102.

In the Tribune Tower Building all electricity for lights, elevators, etc., etc., amounts to 1.5 per cent of the total revenue received from the building. * * * The cost of electricity for operating the Tribune WGN Radio Station and Studio is 2.5 per cent of the total cost of maintaining the Studio. * * * Electricity for the warehouse and dock amounts to 0.7 per cent of the total cost of operating the property."

Power is one of the few commodities the cost of which has steadily decreased while the cost of other commodities has been doubled and trebled. Even during the 1929 depression when the demand decreased materially, and in spite of ever-increasing taxation, the cost of power to the consumer was steadily reduced. The Consolidated Edison Company of New York, serving both gas and electricity to the great metropolis, reports that its tax bill is now (1938) about $1 000 000 per week, or $52 000 000 per yr. It is the largest single item of expense except labor.

The tax increase in recent years is astonishing—as much as 70% in seven years. In 1930, taxes took 12 cents out of every dollar of income. In 1937, taxes took 20 cents of every dollar paid by the consumer for service.

The rates charged by the Company have been lowered sharply in these years, so much so that the bill to consumers was $44 000 000 less in 1937 than it would have been on 1929 rates; but if the Company paid no taxes and the entire tax saving were passed on to the consumers, their bills could be reduced 17% more.

Power production as an industry was practically unknown until the efforts of Edison, Thompson, and their contemporaries, established electricity on a commercial basis about 1883, and it was not until about twenty years later that records were obtainable for comparisons as to the cost of power, its use, and its influence upon the welfare of the country.

TABLE 12.—Cost of Power, Showing Growth of the Power Industry in the United States

Description	1912	1922	1936
Generating capacity, in kilowatts	5 165 400	14 313 350	34 466 000
Invested capital, in thousands of dollars	2 062 655	4 817 000	13 300 000
Thousands of kilowatt-hours of energy generated	11 569 100	44 422 000	108 854 000
Operating cost, in thousands of dollars*	151 270	533 068	934 200
Taxes, in thousands of dollars	13 147	73 772	272 258
Number of domestic customers	3 101 000	10 211 230	21 648 300
Kilowatt-hours of energy sold per customer	264	359	720
Average rate, in cents per kilowatt-hour	8.9	7.4	4.74
Number of people living in electrically lighted houses	14 000 000	44 000 000	89 700 000
Percentage of population	16	39	70
Ratio of investment to receipts	6.85	4.50	6.00
Investment, in dollars per dollar of annual taxes	157.0	65.50	49.0

* Does not include fixed charges.

The economic aspects of the cost of power may be reflected by a few comparisons (see Table 12) which show the growth of the power industry in the United States during the last half century, the increasing additions of the invested capital to the national wealth, and the increasing contributions through taxes to the support of the municipal, State, and Federal Governments.

CONCLUSIONS

Some of the more important conclusions may be summarized as follows:

(1) The total cost of producing power consists of fixed charges and operating costs. Fixed charges are the principal cost in producing hydro-electric power and are also a major item of cost in producing steam power.

(2) The capital cost of power plants, both steam and water power, is variable, depending upon many factors, but principally on the location and nature of service to be rendered.

(3) The cost of power generation is also variable, depending principally on the cost of fuel and the output of the plant in the case of steam plants, and upon the capital cost and the available stream flow in the case of hydro-plants.

(4) Reliability of power supply is an important factor which may affect both the capital and operating costs of power plants.

(5) Steam and water-power plants are seldom economically competitive but are ordinarily complementary if used to best advantage.

(6) When investments are made in large new power plants, the output can seldom be absorbed immediately and, in the case of some of the large hydro-plants, not for many years. In such cases the yearly fixed charges and maintenance costs on the unused part of the plants, less credit for increased economy of operation, if any, must be added to the capital cost of the plant until it is fully utilized.

(7) Particular attention should be called to the difference in cost of steam power from plants designed with full auxiliaries and reserve capacity, and those designed for less reliable service.

(8) Abundance of reliable power is of much greater importance than cheap power from unreliable sources.

(9) The power industry is of increasing importance to the welfare of the nation and has made tremendous contributions to its wealth and income.

DISCUSSION

JOEL D. JUSTIN,[32] M. AM. SOC. C. E. (by letter).—It is hoped that Mr. Whitman's paper, as well as others included in this Symposium, will help to dispel the romance which so often obscures discussions of economics in relation to power. If the public is to secure power at the minimum practicable cost, certain simple rules of economics should govern the undertaking of new projects regardless of whether private capital or Government capital is involved. Thus, if an ill-advised capital expenditure is made, the cost of power is increased, and the public pays for it either as consumer, taxpayer, or investor. Some of these simple rules of economics in relation to power supply are discussed herein.

The capacity available in any given power system should at all times exceed the existing load by a margin (reserve capacity) sufficient to insure continuity of service and, in addition to the foregoing, there should be, as nearly as may be, just enough "surplus capacity" to take care of the growth of load until the next contemplated increment of capacity can be installed and placed in operation. To maintain a proper balance between available capacity and load it is necessary to plan. "Planning" to supply future needs is not an innovation of the last few years as some seem to think. The power companies and, in fact, most industrial corporations have done it for decades. Many of the public utility corporations maintain groups of engineers whose sole function is to determine as nearly as possible the future needs of the system and "plan" to meet them in the most economical manner.

When additional capacity is required its installation should be predicated on thorough economic studies by competent engineers in order to determine the capacity required, the most desirable and economic location for it, and also the kind of capacity that should be installed—that is, whether it should be steam, Diesel, or hydro-electric power. Such a study will involve not only the general design and cost estimates of proposed plants, but also the problems of transmission, distribution, and sub-stations. Sometimes, it will be found that although a huge new steam turbine in a central plant would produce the required additional power at a lower cost at the switch-board, nevertheless, when transmission and distribution are considered, it may be found that the additional annual cost will be a minimum if several smaller, less efficient, units are added at a higher cost per kilowatt in remote plants at local load centers.

Although it may be surprising to some engineers, it is believed that economically the Diesel engine may perform an important function in some large power supply systems. Thus, in the case of a long distribution line, the end of which is many miles from one of the large central stations of the system, if the load on this distribution line increases greatly, the increased demand may be met by enlarging the capacity in the central station and the distribution line. Sometimes, however, it is found that the alternative of installing a

---

[32] Cons. Engr., Philadelphia, Pa.

Diesel plant out near the end of the line is more economical because it is then not necessary to increase the investment in the line.

When considering whether or not a hydro plant, or a steam plant, should be installed, many factors must be given consideration if the most economic solution is to be reached. Mr. Whitman has stated some of these factors. The capital cost of a proposed hydro plant may be so great that the average cost of energy produced by it is greater than that of any steam plant in the system but, nevertheless, by reason of its peak-carrying capacity, such a hydro plant may be the most economical increment of capacity that could be installed in the given situation. One engineer referred to this problem as the hydro-paradox. In other words, it costs more, but it is cheaper, sometimes.

Some engineers, charged with the responsibility of planning development to meet future power requirements, have a leaning toward the biggest and best and may take pride in feeling that their system has the most efficient and largest units. A large unit with a minimum production cost per kilowatt-hour is not always the most economical increment of capacity for a given system. For one thing, fixed charges on unneeded capacity may more than eat up the saving in production cost. The use of extremely large units also increases the reserve capacity which it is necessary to have. A reserve requirement, which has been found suitable in many systems, is that the available reserve at any time should be either equal to the largest unit, or to 10% of the load, whichever is larger. Thus, for a 165 000-kw unit, there should be at least 165 000 kw of reserve capacity ready to go on the line in case of a break-down. For a system having a load of more than 1 000 000 kw, this may be no hardship, but for a system having a load of, say, 200 000 kw, it means that units of such great size are entirely uneconomical in spite of low production cost per kilowatt-hour.

When an additional plant is required, that increment of capacity (usually either steam or water power) should be selected which will result in the total annual cost of power supply for the entire system being lower over a term of years than it would be if any alternative increment of capacity were added.

Throughout most of the United States the development of power systems on an economic basis has resulted in the inter-connected combined power systems which Mr. Whitman has discussed. The power supply of these systems is derived from both steam and hydro-electric plants.

Even some engineers are prone to discuss the thesis: "Is steam power cheaper than water power?" Such questions should be relegated to the high school debating societies because no general and truthful answer is possible. In sections where topographical, water supply, and load conditions are favorable, it is usually economic to supply a part of the requirements of the increasing load by the construction of hydro plants. The peak-load carrying advantages of water power are so great that it appears improbable that any near-by development will crowd the hydro plant out of the economic picture. Thus, in 1922, 31.0% of the total capacity of privately owned public utility plants was hydro capacity. In 1937, the corresponding value was 27.5 per cent. The latter may have been adversely affected by the extensive construction of water power plants by the Federal Government.

Power supply investigations for various systems have convinced the writer that, for most territories, there is a fairly definite economic hydro ratio which may be defined as that ratio of hydro capacity to annual peak load that will give a minimum total annual cost of power supply for the given system.[33] This economic hydro ratio may range from 100% (as in some sections of Canada where fuel is very expensive and suitable hydro sites with abundant water supply are common) to a very small percentage in territories where fuel is very cheap and where favorable water-power sites are almost non-existent. The interesting fact is, that for considerable territories covered by inter-connected systems, the economic hydro ratio appears to be quite constant for that section.

Mr. Whitman makes the statement in connection with a Government hydro project (see heading, "Federal Hydro-Projects") that "it was testified that the Government would pay only 3% for its money, therefore, the rate of return required would be only this rate; whereas, private companies had been compelled to pay about 7% for their money." When all factors are considered, 3% Government money is in reality somewhat more expensive than the 7% private money required by privately owned utilities for capital expenditures.

In order to determine the true cost of money for a proposed Government project some such set-up as the following should be made. (It is herein assumed that Government construction and operation are just as efficient as if the project was privately owned and that in each case the proposed project would be loaded to the same extent):

Cost of Money to the Government for a Power Project Amounting to $1 000 000 (The Term, "Government," as Used Herein Means All Government—Federal, State, and Local):

(1) Interest on Government investment in power project:

3% on $1 000 000 .... $30 000

(2) Taxes on privately owned public utility which Government will have to forego if it builds and operates the project itself; 15% of revenue (in many cases this is more than 16%) which, on a 1 to 6 ratio would be:

15% of $166 700 .... 25 000

(3) Individual Federal income taxes of investors on dividends and bond interest of alternative privately owned project which Government would have to forego if it builds and operates the project itself. Since such investors are ordinarily in the higher than average income groups, this will probably average 15% of the 7% return received by them, or,

1.05% of $1 000 000 .... 10 500

(Carried forward to next page).

---

[33] "Power Supply Economics," by Joel B. Justin and William G. Mervine, John Wiley & Sons, Inc., New York, 1934, p. 142.

(4) State and local taxes on the income of investors which Government will have to forego if it builds and operates the project itself. In Pennsylvania, this takes the form of a personal property tax, 0.4% State plus 0.4% county on values, or, 0.8% on $1 000 000	8 000
Total annual cost of money to Government for $1 000 000 power project	$73 500

Hence, on this basis, the true cost of money for the Government project is 7.35% as compared to 7% for the privately owned project.

Item (3) is the writer's estimate as he does not know of any statistics on the subject. In the case of any individual investor, this item would be the highest increment of the income tax which he pays. There is also the question of multiple taxation in some cases which would be very difficult to evaluate. Item (4) is precise for the Commonwealth of Pennsylvania, except that it does not apply to the securities of corporations incorporated in Pennsylvania, but may vary greatly elsewhere.

Although it is believed that the foregoing tabulation approximates the truth in many cases, it is presented merely to illustrate one of the set-ups which the Government authorities should make as the result of extensive study to determine whether or not it is advisable to construct a Government project. This statement assumes, of course, that the only reason for the Government to build a power project would be to obtain power for the people at the lowest practicable total annual cost.

FRANK H. MASON,[34] M. AM. SOC. C. E. (by letter).—Each author of this Symposium has performed a service in helping to give a broader view of the subject. Professor Barrows covers the field of hydro-generated energy with the exception of pumped storage plants, which are not common in the United States. This paper is valuable in revealing such variations in the cost and the output of different types of plants as the following: The higher head plants normally cost less; the capacity and capacity factor have a great influence on the cost of the plant and the cost of power; and, the increase in size of the plant generally lowers the cost of operation and maintenance in terms of the capacity or the output.

Professor Barrows also gives the reason for, and value of, over-capacity of a plant to some systems, and the advantage of using water power for peak capacity in a combined hydro-electric and steam system. He gives a summary of what other engineers have done and think, as a comparison and aid. Even a casual reading of his paper shows that the variations in cost of a hydro plant and the output are dependent on the locality, the type of plant, and the object of its construction.

Too many people in the past have sought, or quoted, an average price for construction and for generation without knowledge of the requirements of the service, or the location of the plant. The Government proposed to have a yardstick for the measurement of cost. The examples, either because of their large size, the subsidized cost, or the lack of information on the cost, have failed to furnish material for a fair comparison.

---

[34] Chf. Engr., New England Public Service Co., Augusta, Me.

The fifteen years since 1923 have brought about a remarkable advance in the type and knowledge of equipment for hydro-generation and power development construction. Who has brought this about and paid for the cost of present-day advancement? Certainly no one but the private company, the manufacturer, and the private laboratory. If the private company could rebuild its plant with present, up-to-date equipment at subsidized values and with low interest rate, and then operate without much, if any, taxation, a low cost would be obtained; but, after all, the real costs depend on the sale of output and not on a plant's capacity to generate power. Some of these Federal plants for years to come might just as well be back in the woods of Canada because the plants will not have a sale for power. Consequently, the actual output costs will rise, or there will be years of fixed charges to be met.

It has taken years of time and much expense to acquire loads, and to perfect equipment. Even now, the increase in demand for a better and surer type of service, the unknown question of obsolescence, and especially the increased taxation, leave the future unknown. It is certainly a proper time for a complete review of the subject of power costs.

W. V. BURNELL,[35] ESQ. (by letter).—In his paper, Mr. Scharff has made a distinct contribution to the troublesome subject of depreciation. He has lifted the veil of mystery that has long enshrouded the subject by demonstrating that many facts, which hitherto have been determined largely by judgment, are, after all, susceptible of reasonably accurate and reliable determination. If the business of the electric industry is to be governed hereafter in accordance with the facts concerning existing depreciation, much is to be gained from a careful consideration of Mr. Scharff's proposals.

In any forward view of the matter, however, it is incumbent upon the management of electric utilities to inquire also into the regulatory aspects of the problem. No matter how sound and well supported a professional determination of the facts may be, it must first be accepted by the regulatory body and the Courts, before it can safely be adopted by a regulated utility as a business policy.

As to the attitude of these regulatory bodies, if one may judge from the revisions that have been made recently and which are currently being made in the accounting systems which they prescribe, it is leaning definitely in the direction of a radical departure from previous practice. There is ample reason for the conclusion that the commissions, generally, are now in favor of a depreciation policy which is essentially actuarial in nature and based on some application of the principle of life expectancy. Along with this trend of thought, there goes the parallel conviction that the depreciation policy which is to be adopted for the purpose of utility accounting should correspond with the basis adopted for the determination of permissible income.

---

[35] Appraisal Mgr., Stone & Webster Eng. Corp., New York, N. Y.

Depreciation is defined as loss in value. The purpose of depreciation accounting is to provide a means by which the losses may be recouped by the investor. In principle, it matters little how the recoupment is provided for, just as long as the investor receives the income to which he is entitled during the life of the investment and the principal when the income terminates.

Until recently the electric industry, in accordance with the privilege extended to it by most of the regulatory commissions, has seen fit in most cases to follow the retirement reserve policy. To a considerable extent this policy has relieved the present customer of depreciation charges to compensate for losses in value which, although anticipated as a future probability, have not yet occurred. Under this policy, some of the losses brought about by improvements in the art have been assessed against the prospective beneficiaries of those improvements. The tendency now seems to be to require the present customers to accept a much greater share of the burden.

In this apparent transition from one depreciation policy to another, the industry is confronted at once with two important considerations. In the first place, there is a disposition to make a retroactive application of the new rule of the game and, by this process, to assess against the utility a loss in value for which the present investor would have been compensated if the new rule had been in effect hitherto. This is not "cricket" by any means, but the industry nevertheless is confronted with the danger. In the second place, the newly adopted rule implies the necessity of increased annual appropriations to the depreciation reserve and a relatively higher schedule of rates to provide for them.

As to the question of retroactive application of a new rule which deprives the industry unfairly of some part of its property value, there seems to be no available alternative except for the utilities to insist upon their rights. As to the policy to be followed in the future, however, the industry has been "placed on notice" that the old rule may no longer be honored. It may be that a contention can be made successfully against the new rule, but all will agree that at least there is considerable doubt about it.

It may be stated also that the industry is confronted with a number of new competitive aspects of the situation which are purely economic in character. Aside from any such economic aspects, however, and in the light of the regulatory trend alone, would it not be the part of wisdom for the electric utility companies to "drop an anchor to windward" by a careful analysis of their operating charges for depreciation, and also as to the sufficiency of their charges to the customers for service to provide for the higher cost of power which may result from the new regulations?

DANIEL W. MEAD,[36] PAST-PRESIDENT AND HON. M. AM. SOC. C. E. (by etter).—In 1924 the writer was drafted by the Power Division of the Society to prepare a paper on "The Economics of Hydro-Electric Development"[37] for the Spring Meeting on April 9, at Atlanta, Ga. For simplicity the analysis was confined to single independent hydro-electric developments and should perhaps be somewhat modified when considering developments in connection with extensions of properties already in operation and with combined projects having two or more objectives. It is obvious that, when considering new developments made in connection with extensions of power properties already in operation, conditions are somewhat changed. For example, the long and expensive process of developing a market may be entirely eliminated because the power of the new plant, upon completion, may be turned at once into an operating distribution system. In combined properties having two or more objectives, the distribution of first costs and operating costs may be very complex and indeterminate. Appendix A of the writer's paper[38] includes a simplified analysis of "Factors of Economic Expediency"; Appendix B, "Capitol Costs"; and Appendix C, "Annual Expenses."

---

[36] Prof. Emeritus, Hydr. and San. Eng., Univ. of Wisconsin; Cons. Engr., Madison, Wis.

[37] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 158.

The writer has re-examined these analyses and finds no additions which he would make at this time and nothing which he would eliminate. Similar outlines for plants which develop power from heat sources can readily be made. The writer believes that very little difference in opinion is possible among power engineers as to what should, in the general case, be included in such an analysis.

In view of the discussion now before the public as to the actual and relative costs of hydro-electric and steam-electric power, and in view of the pretense of the Federal Administration to establish so-called "yardsticks" to measure the legitimate cost of power as generated by public utilities, it seems fortunate that the subject of power cost is now open to discussion in the form of the present Symposium.

To those familiar with power-cost analysis the subject cannot be regarded as greatly complicated; but to those unable to make such an analysis, the subject is complex on account of the numerous factors which enter into its consideration, all of which must be properly evaluated in order to determine the proper answer to any particular problem.

No simple rule, measure, or criterion can be applied under the great variations in circumstances that occur when the entire United States is considered, and often wide variations of conditions occur within quite narrow geographical limits. This is particularly true when comparing public and private power plants as to first cost and cost of operation.

Mr. Page indicates some of the differences in cost between power plants constructed by public and private agencies such as "taxes," "franchises," and "State and Federal income taxes." The matters of "interest on first cost" of the project and of "interest during construction" are also of great importance and are seldom considered in Federal projects. Even if they are considered, the considerable difference in interest rates (often urged as a condition favorable to public ownership) would make plant and power costs not fairly comparative.

It is unfortunate that the public, including both State and Federal legislators, seems to regard this matter of power costs as comparatively simple and easily determined because, in fact, it is a problem for the trained power analyst. The idea of the average legislator on this subject is illustrated by the following example: About 1910 the State Legislature of Wisconsin passed a water-power law by which an attempt was made to confiscate the privately built water powers of Wisconsin on the ground that they were natural resources which legally belonged to the State. Prior to the passage of this law, extended hearings were held by a joint committee of the House and Senate of the State and the writer spent considerable time in trying to explain to this committee the basis of hydro-electric and steam-plant power costs. Among the questions asked the writer, was: "How much does it cost to develop a horse-power from water?" The writer explained that such cost would vary largely with local conditions, size of plant, nature of equipment, and the point at which the resulting power is to be measured. For example, the cost of installation might vary from $35 per hp, measured at the turbine shaft of a high-head impulse wheel in the Far West to $350 per hp, for a low-head plant in the East with power measured at the switch-board of the customer, say, 100 miles from the power-house; and that similar differences in steam-power cost depended on the size and character of equipment and the great variation in cost of fuel and labor at different points in the country. The writer thinks that it was the opinion of at least the so-called "progressive" members of the Committee that he was endeavoring to obscure the issue rather than to clarify it; when, in fact, he was doing his utmost to present this somewhat complex subject fairly and in the simplest language possible. He explained that the question is similar to such questions as, "What does it cost to build a house?" and can be answered only with specific conditions in mind.

---

[38] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 186.

Assuming that the writer's estimate of hydro-electric costs is fairly accurate, at least for the purpose of illustration, it is quite evident that the $35 per hp cost of power development at the turbine shaft in the Far West, high head plant is not an honest nor a far "criterion" or "yardstick" for the cost of power development from a low-head plant in the Central or Eastern States where the actual cost of development was $350 per hp, delivered at the switch-board of the customer 100 miles distant. Neither is the reverse true.

In discussing "Public Ownership of Power" and the so-called "yardstick," Arthur E. Morgan, M. Am. Soc. C. E., states[39] that "it is imperative that records and accounts be honest, and fair and open, and that there be no hidden elements of subsidy. The very fundamental element of such comparison is honesty, fairness, and openness in measurement." He might have added that the circumstance of development of all plants compared to this "yardstick" should be essentially similar or identical.

It is obvious, of course, that all plants competing for business in any given community must furnish power at a competitive price regardless of their cost of construction or of the cost of delivering power. If they cannot compete they must go out of business. There cannot be any real competition between Federal and privately owned plants, however, as the latter are regulated and controlled by the Government and can be eliminated at any time by Government fiat in which the factors that of necessity control private investments may receive little consideration. The United States attorneys on the case between the TVA and the private utilities which was heard at Chattanooga, Tenn., in 1937, stated that, if Congress so directs, the Federal Government can furnish power for nothing. This is doubtless true, but in so doing the Administration can scarcely expect engineers or even the public to accept such prices as a fair and honest "yardstick" for the measurement of public utility charges.

---

[39] *Atlantic Monthly*, September, 1937, p. 342.

The so-called "yardstick" is purely fantastic and actually meaningless except as a political catch word or to the man who assumes that the problems of the cost of power plants and of power generation are simple, and of such uniform and constant character under all circumstances that a criterion can easily be established that is widely applicable. This idea is entirely erroneous. All power engineers know that, in general, the only way to determine with any degree of accuracy the fair cost of a power plant or of power generation is to determine all the circumstances under which the power is generated, delivered, and used.

The determination of the cost of a power plant and the fair price for the power which it furnishes, by building a competing plant under entirely different circumstances and operating it together with many other objectives whereby both the first cost and the cost of operation will be hopelessly obscured, is an idea which would never occur to an engineer. Such a method of determining power costs is perhaps fairly comparative to the way in which most political questions are now solved.

While the determination of power costs is complicated to the layman, the principles involved are so simple that in the main the writer would expect little difference among qualified engineers as to those matters which must enter into any fair consideration of the costs from any single plant or combination of plants. Differences in opinion concerning power cost arise, however, not in the theory but in the application of principles of concrete cases.

When a hydro-electric power development is only one of a number of objectives undertaken in a common development and it becomes necessary to separate the costs of power development from other objectives, real or imaginary, that are included in the combined project, there probably always will be difference of opinion, even among engineers, as to the proper proportion of costs to be distributed to the various objectives. Fair and just proportion of charge, which should be assigned to any one objective, cannot always be fully demonstrated and will always result in a wide difference in opinion.

For example, in the Grand Coulee project on the Columbia River, in Washington, the objectives are said to be navigation, flood protection, irrigation, and power. In the Tennessee Valley the objectives are said to be navigation, flood protection, power, reforestation, erosion prevention, the manufacture of fertilizer, and national defense. In each case power is assumed to be incidental to more important objectives that are legitimate undertakings of the Federal Government, which cannot undertake power development as a main or principal objective. It seems quite evident that in all cases where more than one objective is declared in the enabling act, the distribution of fair and just costs to each objective is difficult, if not impossible, and must to a large extent, be, and remain, uncertain. For this reason the attempt to establish, as a criterion or "yardstick" for measuring either the cost of development or the cost of power, any power plant having an uncertain cost of construction and an equally uncertain cost of operation is fallacious. Such a criterion is of no value in measuring the true or fair cost of development of the cost of power for plants built under quite different circumstances.

It is evident that there may be various points of view in particular cases. If, for example, the present Tennessee Valley improvements, in their present form, were needed and warranted for flood-protection and navigation purposes, and after construction and completion, power plants were added, the fair cost of development might include only power-house equipment, transmission, etc. Such cost certainly should include interest, engineering, supervision, freight and mail subsidies, etc. Even then it could hardly be considered a fair "yardstick" to measure the cost of power to an independent development where power only is the main objective and many other factors are involved.

In the Tennessee River case the high dams are probably an actual detriment to navigation when compared with low dams built purely for navigation purposes, and have only a limited value for flood protection. As a matter of fact, the height of dams was undoubtedly determined from the power standpoint. Suitable navigation and all flood protection warranted by the condition on the Tennessee River could have been furnished at a fraction of the cost which has apparently been charged to these objectives; and the objective of water power apparently has been charged with less than one-third the costs which the writer believes should be fairly attributed to it.

Neither the Federal Administration, Congress, the State legislatures, nor any other authority, corporation, or individual, can in any way establish a fair and just measurement of what power will cost, or the fair and equitable price at which it should be reasonably sold, except by considering the individual circumstances of construction and operation.

In other words, the so-called "yardstick" for the cost of power is a purely fantastic and impossible ideal, and when attempted is only fairly applicable to the plant or combination of plants created for such an unnecessary purpose. Such a term sounds well to the layman and, therefore, is useful to the politician to mislead the people and to secure popular approval; but it is practically meaningless to the engineer except perhaps in the case of plants when the conditions of duplication may be so uniform that almost identical results can be expected to obtain.

False estimates of the cost of power for either Federal, State, or private power plants will only deceive the engineer where costs are unknown or where "hidden elements of subsidy" cannot be determined. A clear and honest statement of facts and conditions or an investigation of these conditions, if permitted, will demonstrate to any qualified engineer or board of engineers, the fair cost of a power plant or power plants and the fair cost of power which such plants can or do deliver to their customers.

On the other hand, by unfair and dishonest statements and inaccurate or erroneous records of conditions and costs, the public may be deceived—"all of the public part of the time and part of the public all of the time."

The writer agrees with Mr. Page that it is time for engineers "to assist, honestly and whole-heartedly, in seeing to it that the public weal is placed foremost among the objectives of the power industry." He also believes that there is no less of a duty due from the administration and its officials to deal frankly, honestly, and intelligently with the public.

Mr. Page's paper is a frank and fair statement of the factors that enter into the problem of power costs, and the writer finds little to which he desires to take exception. He is unable to agree, however, with the apparent assumption that many of the "large Federal multiple-purpose projects" are warranted at this time, even on the basis of doing something possibly to aid in recovery from the depression. To add to the burden of the taxpayers of the nation the enormous sums made necessary by many of these entirely unwarranted projects can only prolong the depression and make recovery more difficult. The lack of information concerning these Federal Government multiple-objective projects and district power plants leads to the conclusion that they have not been duly considered but have been hastily adopted as projects which would furnish opportunities for labor and might possibly aid in recovery from the depression. It is evident that in most, if not all, cases there has been no proper and detailed consideration of their plans, cost, desirability, necessity, or soundness prior to their adoption and authorization. Under such conditions it must be expected that many ill-conceived and unwarranted projects have been included and that great waste will be entailed.

Undoubtedly, much misinformation has been issued on the subject of power costs—some of it propaganda, to mislead the public for or against either private or public ownership and operation of power plants. Some of the information on this subject is furnished without sufficient explanation to limit its use in a proper manner.

A committee of the U. S. Chamber of Commerce in 1936 published a table[39] entitled "Federal Power Projects" which gives: (1) The name of the project; (2) the approximate expenditures to June 30, 1935; (3) the ultimate cost (estimated); and (4) the ultimate horse-power (estimated). Any one familiar with power matters should know that all these projects are multi-objective in character and a reading of the report so indicates; yet in a paper read at the Sixth Midwest Power Conference held in Chicago, Ill., on April 22, 1936, this table was taken, unmodified, as a basis for estimating the costs of Federal hydro-electric power plants and power costs. This unwarranted use of the data destroys almost the entire value of an otherwise excellent paper and leads to suspicion of intended propaganda adverse to Federal hydro-electric power projects. The paper is so denounced in a "letter of submittal" and in a report sent to the President of the United States by the Chairman of the New York Power Authority[40] in which the public development of hydro-electric power projects is presented in an equally fair and logical way.

---

[39] Report of Committee on Water Resource Policies, March, 1936, p. 22.

[40] H. R. Doc. No. 52, 75th Cong., 2d Session.

Every power engineer knows that the profession is entirely ignorant of the probable cost of those Federal Power Projects, much less as to what costs will ultimately be charged to them by the Federal Power Authorities. It is doubtful if the public or even the Engineering Profession will ever know what fair cost should be attributed to these power installations or power costs in these Federal multi-objective installations where many of the objectives are largely imaginary and often introduced only to assure the legality of Government development.

The writer believes that the question of hydro *versus* steam power plants can never be settled by such general one-sided and unfair presentation based on unknown or imaginative data. All power engineers know that each problem is a question of local conditions and must be studied and solved as such. After all, the power market or the probable demand for power should be the true reason for any installation and this important matter is ignored in many of these discussions as though power were of value, whether used or not.

Even if the first cost of the development of these projects could be established, it is certain that quite a different result would be found if the delays and consequent cost of market development were considered. Many a private development has failed of success due to long delays in the establishment of a profitable market. In Federal projects such expenses seem never to be considered, as they can be met at the expense of the taxpayer, who will probably never appreciate how much he is called upon to pay for the development of unwarranted and ill-advised Government projects, not only for power but also for navigation, irrigation, flood protection, and recovery.

It is certainly true that honesty, intelligence, frankness, and fair dealing should be introduced into all public and private relations; for to the present time neither Government authorities nor business interests have a monopoly on either honesty and frankness or misrepresentation and propaganda.

A. G. CHRISTIE,[41] ESQ. (by letter).—The elements entering into the cost of heat-generated energy have been clearly described in the paper by Messrs. Hirshfeld and Van Duzer. Their cost estimates represent a painstaking analysis of available data and a careful selection of average values for inclusion in the curves. Messrs. Hirshfeld and Van Duzer leave little for discussion other than to amplify some of the factors they have considered. They emphasize the fact that any costs presented in the paper are not representative of the industry as a whole but are only the logical deductions that one derives from the data assumed in each case. They stress the fact that conditions of location, load, and fuel vary so widely that costs under the several conditions cannot be equal; nor are costs truly comparable without consideration being given to correction factors for these variables. The methods of applying corrections are also stated.

Consider fuel costs, for example. Messrs. Hirshfeld and Van Duzer assume 15 cents per million Btu. In many localities fuel may be obtained for about 10 cents per million Btu. In such a case, the fuel cost would be much less than that assumed by Messrs. Hirshfeld and Van Duzer for the same station efficiency; but there will be some question as to whether the expected capacity factor of the plant with this low priced fuel would warrant as efficient and as expensive a plant as Messrs. Hirshfeld and Van Duzer assume. If a less efficient and less expensive plant is used, both fuel costs and fixed charges will be affected. At the other extremity, the writer has designed a plant for a foreign location where the fuel cost was about 50 cents per million Btu. Considerable money was spent to secure maximum efficiency from the equipment installed at this plant. A diagram[42] published in January, 1938, shows the remarkable reduction of coal per kilowatt-hour over the last few years. The curves indicate large increases in total kilowatt-hour output with almost stationary total coal consumption.

---

[41] Prof. of Mech. Eng., The Johns Hopkins Univ., Baltimore, Md.

TABLE 13.—UNIT COSTS OF THREE TYPICAL STEAM-ELECTRIC POWER PLANTS

Item No.	Description	Cost,* in Dollars per Kilowatt of Capacity		
	(1)	Plant A (2)	Plant B (3)	Plant C (4)
1	Plant capacity, in thousands of kilowatts	70	70	185
2	Number of units	2	2	6
	Cost per Kilowatt of Capacity, in Dollars:			
3	Land, fill, etc.	4.55	2.94	12.60
4	Building substructure	15.03	5.33	4.97
5	Building superstructure	3.17	8.95	21.40
6	Building trim	1.15	0.88	1.78
7	Building equipment	0.45	0.35	2.72
8	Mechanical equipment	24.45	22.38	30.03
9	Electrical equipment	24.90	20.56	28.68
10	Service equipment	7.85	2.80	16.45
11	Substation	4.16	1.40	10.67
12	Engineering and construction	27.12	17.46	20.42
13	Total cost per kilowatt	112.83	83.05	149.72

* Except Items Nos. 1 and 2.

Referring to investment costs, Table 13[43] gives data on the cost of three different stations. Plant A, situated on the Ohio River, has the lowest coal cost but the highest cost of substructure (probably due to the incidence of floods). Plant C, in a locality with high land values, has also the highest coal costs. Plant B has fuel costs intermediate between Plants A and C. Note that: (1) Building substructure varies from $4.97 to $15.03 per kw; (2) building superstructure from $8.17 to $21.40; (3) mechanical and electrical equipment from $42.94 to $58.71 per kw; and (4) total cost from $83.05 to $149.72 per kw. Attention is drawn to such actual values to demonstrate the influence of such different factors as location, fuel costs, and foundations upon individual items of plant cost and consequent influence upon total plant cost.

Plant locations are often chosen for reasons that outweigh sub-soil conditions. Thus, Cahokia Station, at St. Louis, Mo., is supported upon very long piles, whereas the Avon Beach Plant near Cleveland, Ohio, is built upon solid rock which had to be blasted away to make room for proper cooling water intakes.

---

[42] *Power Plant Engineering*, January, 1938, Fig. 1.

[43] "Power Supply Economics," by Joel D. Justin, M. Am. Soc. C. E., and William G. Mervine, John Wiley & Sons, Inc., New York, N. Y., 1934.

It has been suggested that the total cost could be decreased and the fixed charges lowered by the elimination of the building superstructure. This part of the plant cannot be eliminated entirely for obvious reasons. In certain localities some savings may be effected by this change. In an Australian plant designed by the writer only a roof is provided over the plant to keep off the sun and shed water during a few weeks per year of rain. Outdoor plants are not justifiable in cold climates.

Sometimes plant location and resultant construction cost are fixed by factors other than simply the supply of power. Thus, all plants supplying both power and district heating are located and planned with reference to the heating load. A unique case of the influence of external factors occurs at the power plant in Edmonton, Alberta, Canada, which is adjacent to the city's water-works and filter beds, on the Saskatchewan River. Water is pumped through the surface condensers of the power plant before delivery to the settling basins and filters of the water-works. In winter, vacuum is regulated to provide water at 50° F to 60° F to the settling basins as desired. This water does not cool below freezing in passing through the filter beds and in the pipes under the streets to the various consumers. Although low temperatures are experienced at times, this waste heat from the exhausts of the steam turbines in the electric plant prevents losses from frozen water pipes throughout the city, and even aids in better functioning of the sewers and sewage disposal plant. This system has also been embodied in the new plant now building at Edmonton.

Another factor in the initial cost of plant is the degree of expediency in its construction. Overtime added $8 per kw to the cost of one plant with which the writer was associated, owing to the urgent need of this plant capacity, and union rates for overtime work.

These facts support the contentions of Messrs. Hirshfeld and Van Duzer that every station is an individual problem and that the designer of a power plant must analyze and balance the effect of cost variables before arriving at a design that will produce power for the least total cost.

Even when such a plant is completed the costs secured may be modified by changes in assumed conditions, such as modifications of load curves, changes in fuel costs, inter-connection with other systems, or supersedure, by more economical plant on other parts of the system. For instance, Gould Street Station, in Baltimore, Md., was designed to take a large part of the electric system's base load. However, the subsequent development of the Safe Harbor Hydro-Electric Plant has completely upset the economic assumptions upon which the Gould Street Station was planned.

An analysis of the distribution of costs in the paper for the 400-lb, 600-lb, and 1 250-lb plants, with 40% annual capacity factor and average lower costs, indicates that fuel constitutes approximately 26.2% of costs; labor, 7.5%; maintenance and supplies, 3.6%; fixed charges, 53.7%; and general expense, 9 per cent. The predominance of fixed charges as an element of production cost is evident from such data. Fixed charges may be reduced as already suggested by minimum building structure, simplicity, and standardization of design, by inter-connection, and by avoidance of undue haste.

Messrs. Hirshfeld and Van Duzer indicate that whereas the cost per kilowatt of steam and electric generating equipment has tended to decline, the cost of electrical switching, protective, and transforming equipment has increased, leading to a constant total cost over a period of years. This has been a general experience of plant designers.

It has been suggested that lower plant costs might be secured by the adoption of certain standardized designs for steam plant equipment. Some progress has been made in the matter of standardized turbine sizes and operating conditions in Great Britain, where 650 lb, 850° F, are used widely for plant conditions, with 30 000-kw turbines at 3 000 rpm and 50 000 to 60 000-kw units at 1 500 rpm. Little progress has been made in standardization in the United States owing to the prevalence of superposition, the development of condensing turbines of greater capacity at 3 600 rpm, and the increased pressures and temperatures used in the newer stations. When, and if, these developments are complete, consideration should be given to standardized equipment; but standardization tends toward stagnation. Decreases in the cost of production have followed from pioneering which has always been an expensive undertaking to those who depart from accepted conditions.

Messrs. Hirshfeld and Van Duzer do not consider reserve equipment, which is particularly needed in the case of an isolated plant. When a system has several plants, reserve equipment must be provided in one of these and the cost of maintaining this reserve must be spread over the system output. System inter-connections permit the use of less reserve on an individual system and thus tend to reduce production costs. The authors have confined their paper to production costs only. The public thinks only of the bills they pay. The cost of distribution service and of transmission are usually equal to, or several times greater than, production cost. For instance, the cost of meter rental, meter repair and calibration, meter reading, billing, and collecting is frequently stated as $6 per customer per yr. If this is a domestic customer whose total consumption is 600 kw-hr per yr, the cost of this service alone is 1 cent per kw-hr. In other words, customer service equals or exceeds production cost in the case of many domestic consumers. The consumer's attention should be directed to means whereby these larger items of service and transmission costs may be reduced, rather than to the low charges for production alone. Greater individual consumption by all customers will greatly lower their costs of service.

At the moment, Diesel plants have an advantage over steam plants when small capacities are needed. However, maintenance increases rapidly with age and the useful life is not great.

In the discussion of future possibilities Messrs. Hirshfeld and Van Duzer refer to a new "fuel cell" which is under development. Engineers will be interested in more complete information on this interesting research.

Messrs. Hirshfeld and Van Duzer have presented a clear unprejudiced analysis of the cost of heat-generated energy. This discussion cannot be closed better than by quoting their last sentence: "It would seem that the chances for continued reduction of total power cost at the fuel burning generating plant are indeed very large."

WILLIAM E. RUDOLPH,[44] M. AM. SOC. C. E. (by letter).—The Second Symposium on Power Costs is a compilation of valuable data and conclusions as applied to electrical energy generation in the United States. The writer feels that one might go a step further with the discussion by carrying it into Latin-American countries, where important power-plant construction continues in progress, in many instances under the direction of North American engineers and with equipment supplied by North American manufacturers. For, whereas power problems of the more densely populated regions of Latin-America have been solved in much the same manner as in the United States, there would appear to be considerable diversity of practice in interior regions where the demand for power comes principally from the mining industry. In one country—Bolivia—for example, two leading mining companies adopted opposite policies during 1937; one arranged to operate its mines and mills almost entirely by water power, relegating existing Diesel plants to stand-by, "because of the high cost of transporting fuel oil and repair parts"; the other installed Diesel units for operating its principal mill, "to secure maximum safeguard against interruptions of service." Under such circumstances, executives of Latin-American mining enterprises, where expenditures for power generally range between 25% and 33% of the total costs, should find good "food for thought" in this Symposium.

Two important features of the background affecting both capital investments and operating expenses in Latin-American countries are quite different from those in the United States, as follows:

(1) Labor costs are considerably lower. Depreciation of certain Latin-American currencies in terms of the dollar has accentuated this condition in some countries (Venezuela being a noteworthy exception).

(2) Materials costs are likely to be higher, particularly on manufactured products and fuel, because of transportation expenses and import duties.

In mountainous regions away from the coast, these factors contribute to make the comparison between hydro energy on the one hand, and steam or Diesel energy on the other, more favorable to the former; and yet, even here, the two forms of generation are complementary rather than competitive.

A more recent example of hydro-electric plant construction costs is the Kilpani Station on the Rio Yura, in the southwestern part of Bolivia. This installation, with a firm capacity of 4 000 kw, was placed in operation during May, 1937, to supply current to mining establishments at Potosi and Pulacayo, and is typical of plants in mining districts where relatively small tonnages of ores of higher priced metals (in this case, tin and silver) are treated. It utilizes a head of 985 ft, having slightly less than 2 miles of canal, and 4 000 ft of penstock. Its unit cost of $74 per installed kw, exclusive of transmission lines, was divided as follows:

---

[44] New Canaan, Conn.

Description	Cost	Percentage of Total
Dam	$ 2	3
Waterway	36	49
Power-house and equipment	27	36
Roads, etc.	8	11
Land and water rights	1	1

All these unit costs are lower than the costs for the composite of seven higher head plants tabulated by Professor Barrows, except that of road work which is four times as large. This outstanding item reflects ruggedness of terrain and inaccessibility of the region in which the plant was built, factors which hold not only in most parts of Bolivia, but also throughout the Andes.

Obviously, lower costs of dam and waterway, as compared to those in the United States, were due to lower wages, which at official peso exchange in Bolivia at that time averaged about 35 cents U. S. currency per day for peons, and about 75 cents for skilled labor. The dam was earth with a clay core, and the canal was masonry and concrete with rock and sand convenient to the site; and these items benefited most from such labor rates. That power-house and equipment costs were lower than in the United States was due to a temporary condition whereby machinery was purchased from German manufacturers at extremely low prices, through the use of export marks. However, inability of these manufacturers to guarantee early deliveries at the present time, and unfortunate experiences with some of the equipment which they have supplied, would indicate that North American manufacturers have in no way lost their South American market. Costs of land and water rights were low because the site was in a region of 14 000 ft altitude inhabited only by Indian communities.

Attendance and maintenance expenses of operating water-power installations in Latin-America are generally lower than in the United States, again because of the lower scale of wages. However, the item of depreciation in the case of plants furnishing power for mining enterprises, must include consideration of the depletion of ore reserves, causing ultimate loss of load. On the other hand, operators of steam and Diesel installations away from the coast must cope not only with first cost of oil or coal, but also with high transport expenses from the nearest seaport. For the greater part mines are located at elevations of 9 000 to 16 000 ft in the Andes, and the crustal movements which here caused rock structures to become impregnated with veins of metals also provided the steep gradients which permit power to be generated from falling streams for extracting such metals. Rise and fall matter little to a high-tension line, but the toll which such rise and fall exact upon the delivery of oil or coal to remote spots in the Andes represents no small item of the cost of producing Diesel or steam power.

The hydro-plant installation in mining regions of the Andes often has the disadvantage of being remote from the center of operations, entailing difficulty of access for replacements or repairs. Hence, unscheduled interruptions, while less frequent than at Diesel and steam plants, are likely to be considerably more costly because of time losses. Destructive landslides and floods sometimes result from heavy showers in these regions of seasonal rainfall, and abnormal droughts also occur at long intervals. Against such emergencies and transmission-line interruptions, enterprises having only a single source of water energy find it advantageous to install additional Diesel or steam units, or, as is more often the case, to hold in reserve the Diesel or steam units which probably preceded the hydro-plant. Most feasible, economically, is the combined installation in which the Diesel or steam units carry only occasional peak loads during normal years when there is plenty of water, but where they carry the base load during dry years when it is necessary to conserve storage for the minimum stream-flow period just prior to the next rainy season. Inter-connected systems are rare in mining regions, due to obstacles of distance; a recent interconnection involved the installation of frequency changing equipment.

Investments in power plants so large that the output cannot be absorbed immediately are rare in Andean mining regions, because of the high rate of return upon capital required for projects in foreign countries. Much of the expansion in South American mining enterprise during more recent years has been paid for out of current earnings, and with the application of this practice to power plants, the large project is likely to be deferred, while a group of smaller projects, although less advantageous in the aggregate, might proceed. These larger projects may not count upon Government aid, as part of public works programs to reduce unemployment, most Latin-American countries lacking both the money and the need for such expenditures.

Louis Elliott,[45] Esq. (by letter).—The analysis presented by Messrs. Hirshfeld and Van Duzer gives as good a view of thermal-plant energy cost as is possible within the limits of a short paper. With the assumptions made, the stated range of energy production costs, as summarized in curve form in Figs. 2, 10, 13, 14, and 16, gives a reasonable idea as to what is to be expected from steam and Diesel stations in the United States. General considerations, and detailed factors bearing on energy costs, are well covered by the authors. It is particularly desirable to call attention, as is done in the paper, to the magnitude of general overhead—assessed at from 10% to 25% of specific production costs and fixed charges. These overheads, discussed under Group 3, are summarized in the "Introduction."

Engineers studying and utilizing the data presented will doubtless keep in mind that the costs cited cover a wide range with respect to the assumptions made, but apply, as to investment basis, to only one unit cost of plant—$100 per kw of capacity. Therefore, in considering energy costs derived, allowance must be made for spare capacity, which is necessary on every power system, as well as for any variation of unit investment, under actual conditions, from the $100 assumed as a round figure.

Papers of the character presented by Messrs. Hirshfeld and Van Duzer—and this remark applies to sections of the Symposium covering hydro-electric as well as thermal-electric stations—are of general educational and historical value, but should be used with caution as a guide in studying any specific problem. It can scarcely be too strongly emphasized that in analyzing a specific case and determining the economic type and size of a power development, only general guidance can be obtained from a broad study of this kind, and that the most careful analysis of special conditions obtaining, detailed estimates of costs and economies, and broadest judgment, must be brought to bear before a proper decision can be reached. Such a study, for any given case, calls for a command of the best information with regard to modern power equipment and systems, and familiarity with the technical tools of study, such as the various forms of load and duration curves.

---

[45] Cons. Mech. Engr., Ebasco Services Inc., New York, N. Y.

The "art" of designing and operating a power system, whether it be supplied by hydraulic or thermal plants, or by a combination of the two, has become a quite highly developed specialty, and analyses and decisions with respect to power development should not be entrusted to men who have not, through years of training and experience, become thoroughly conversant with the body of data and practice that has been developed. Investigations and reports with respect to power systems or developments, founded upon elementary conceptions and incomplete data, or made on an emotional basis, may well arrive at erroneous conclusions.

H. G. GERDES,[46] M. Am. Soc. C. E. (by letter).—All opinions advanced and estimates made are entirely those of the writer, and all data cited have been taken from published sources. Statements made herein have neither been approved nor disapproved by the Federal Power Commission.

Natural Basis of Complementary Use.—The principal thesis expressed by Mr. Whitman—namely, that the cost of power from combined steam and water power sources is frequently lower than from either source alone—is a paradox, the answer to which, unfortunately, does not appear to be quite clear to the public at large.

In view of recent apparent controversy between advocates of steam and water power, the fundamental principle cannot be emphasized too often that steam and hydro-power sources are more often naturally complementary rather than competitive. This affinity proceeds out of the extremely varying public demand for electricity, whereby engineers are enabled to couple unlike sources of power together in varying degrees to meet this demand with greater economy than from either source alone.

An exception to the rule of complementary economy of unlike power sources occurs where a constant power source such as Niagara Falls attracts a constant power consumption load of like nature. Exceptions, not to the rule, but to the practice of incorporating a steam plant as one of the unlike power sources, occur in the Pacific Northwest where base-load, low-head hydro-plants on the larger rivers may be combined with peak-load, high-head storage hydro-electric plants on near-by mountain streams.

Phases of Combined Power Use.—Growth in the development of combined power use has been marked by many changes, generally characterized, however, by exhibition of the complementary function described. In California, steam plants have successively served major hydro-systems as load center stand-by capacity, peak-load capacity, and latterly as base-load carriers. In the Northwest, steam plants have been constructed on hydro-systems as peak-load carriers, as stand-by reserve, and as quickly added increments of capacity. In the Southeast, steam plants have largely functioned as stand-by reserve and intermediate incremental construction on systems that are predominantly hydro-electric.

---

[46] Cons. Engr., Harza Eng. Co., Charleston, S. C.

In the Middle Atlantic section of the United States, where factories operated by steam power were common before the opening of the electrical era, the growth in central station steam capacity by incremental steps has been a natural evolution, and the complementary advantages of hydro-power have been realized only in recent years.

Factors Favoring Combined Operation.—Peak-load hydro-plants have been more often economically feasible in large sizes of 50 000 kw and upward. Low unit cost demands a large installation, which may be so greatly in excess of the reliable stream flow as to be available only a few hours per week. Interconnection of utilities into large systems increases the usefulness and economic feasibility of such peak-load hydro-plants both by allowing large incremental steps in new capacity and by permitting hydro-peak operation on a higher and sharper weekly load peak in which the same number of stream-flow kilowatt-hours available may be utilized in a shorter time, making firm a larger capacity.

Quite properly, Mr. Whitman remarks that the cost of furnishing peak power by steam is expensive. A renewal of search for peak-load, hydro-plant sites may be expected as soon as load growth and super-position complete the conversion of certain existing obsolete steam plants into base-load carriers.

Combined Hydro-Steam Energy Cost.—Two fairly typical illustrations, drawn from the operations of hydro-steam systems, are presented herein. In these systems the total load is large and the annual peaks both high and sharp. The load will absorb without waste, large blocks of river-run fuel saving power; hydro installations with capacities as great as ten times the low stream flow have been made, and the determining factor is usually the kilowatt-hour storage available to firm the plant capacity on the system peak.

It will be understood that although the data given are believed typical and fair, many simplifying assumptions have been made to bring the examples within the bounds of a simple comparison for the purpose of this illustration. The cost data are comparative and do not include items not affecting the comparison, such as general overhead, etc.

Example 1.—On a large Eastern combined power system, a peak-load hydro-plant of one-third the total system capacity operates at about 20% load factor (1 750 kw-hr per kw-yr) to cover the system weekly peak load. Additional stream flow, in excess of required peak-load storage, averages 3 600 kw-hr per kw of installed capacity annually. The annual load factor of the system is about 50% and the resulting annual load factor of the steam plant is 44.5 per cent. Typical fixed and operating costs have been assumed, as shown in Table 14 for the purpose of illustrating the cost of combined energy generation and delivery to the load center as compared with the cost of serving an independent portion of the same load by either means alone. The steam station is assumed to be at the load center.

From Table 15(*a*) the comparative cost of combined steam and hydro-energy delivered at the distribution network is seen to be 6.24 mills per kw-hr (Item No. 10) as compared with 6.85 mills (Item No. 7) for the entire steam generation, resulting in a saving of 9% (Item No. 11). On a 3 000 million kw-hr annual output system, the indicated saving of 0.61 mill amounts to the substantial sum of $1 830 000 per yr.

TABLE 14.—TYPICAL EASTERN HYDRO-STEAM; ASSUMED CAPITAL AND ANNUAL CHARGES ON DEPENDABLE CAPACITY

Item No.	Description	Capital cost, in dollars per kilowatt	ANNUAL COST								Total
			Fixed					Operating			
						Total		Operation and Maintenance			
			Percentage return on investment	Taxes and insurance, in percentage of total cost	Percentage depreciation	In percentage of total cost	In dollars per kilowatt	Constant, in dollars per kilowatt	Variable, in mills per kilowatt-hour	Fuel,* in mills per kilowatt-hour	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)
1....	Hydro-electric power plant	200	6	1.5	1	8.5	17.00	1.60	....	....	18.60
2....	Transmission and reception	40	6	1.5	1	8.5	3.40	0.40	....	....	3.80
3....	Steam power plant.......	120	6	2.5	3	11.5	13.80	5.00	0.30	2.25	18.80+2.55

* $4.50 coal at 1 lb per kw-hr.

Based on the following plant and load data, the typical load factor diagram in Fig. 33(*a*) shows the position on the annual load diagram of the three classes of power available:

$$\text{Hydro-plant peak-use factor} = \frac{1\,750}{8\,760} = 20.0\%$$

$$\text{Hydro-plant fuel-saving use factor} = \frac{3\,600}{8\,760} = 41.0\%$$

$$\text{Total hydro-use factor} = 61.0\%$$

$$\text{Steam plant use factor} = \frac{7\,790}{8\,760 \times 2} = 44.5\%$$

$$\text{System load factor} = \frac{1\,750 + 3\,600 + 7\,790}{3 \times 8\,760} = 50.0\%$$

$$\text{Hydro-plant energy} = \frac{5\,350}{8\,760 \times 3/2} = 40.8\%$$

$$\text{Steam-plant energy} = \frac{7\,790}{8\,760 \times 3/2} = 59.2\%$$

Total energy 100.0%

The three classes are as follows:

(1) Firm hydro-energy rendering the installed capacity firm on the weekly load curve of the system (assumed at 1 750 kw-hr per kw, or 20% plant factor);

TABLE 15.—COMPARATIVE COST OF COMBINED ENERGY GENERATION

Item No.	Description	Capital cost, in dollars	Percentage of capital cost	COST OF POWER			
				In dollars per kilowatt-year	Mills per Kilowatt-Hour

22	Total, ready to distribute*	...	...	...	1.81		
23	Percentage of saving through combined use	...	...	...	11.0		

* Includes only the comparative items stated. † 74.4% load factor (6 520 hr). ‡ 13.4% load factor (1 170 hr). § Only 20% load factor hydro firm.

(2) Excess hydro-energy available during months of high stream flow, carrying the base load during the time available (assumed as 3 600 kw-hr per kw per average yr); and,

(3) Steam energy carrying base load and semi-peak during months of high stream flow (assumed as the 7 790 kw-hr per kw-yr shown on the annual load curve of the system).

The foregoing substantial saving is made although the hydro-investment is $240 per kw as compared with $120 for steam capacity.

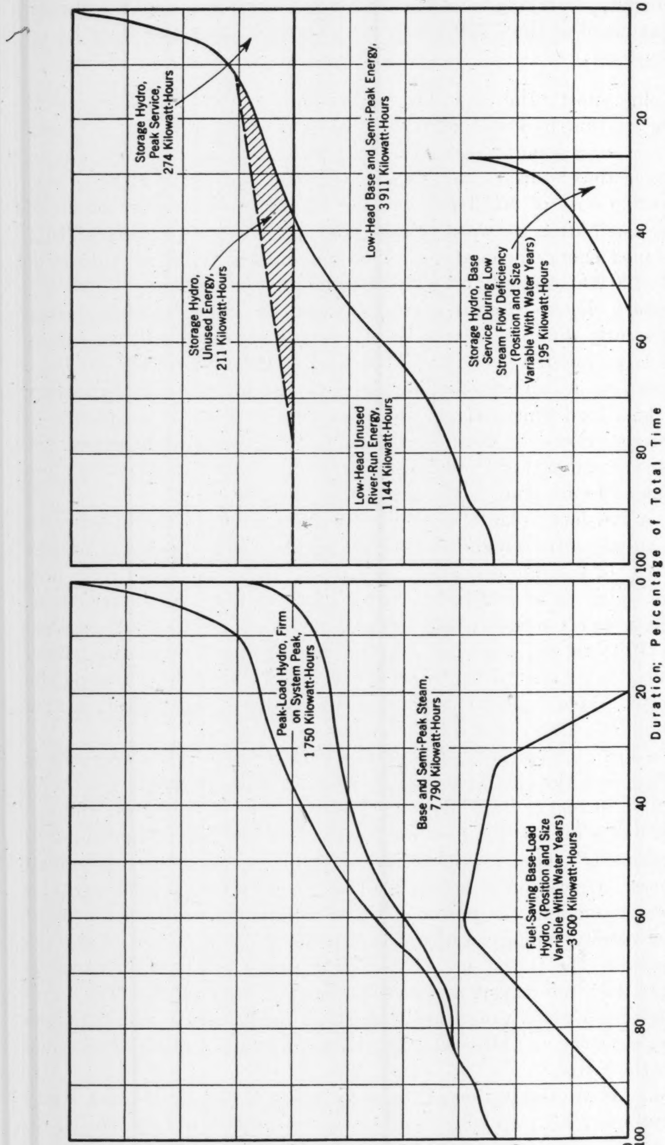
Example 2.—On a somewhat smaller Eastern system in which conditions are similar except that hydro-capacity cost is only $145 instead of $200 per kw, with an operating cost of $0.80 per kw, the comparative cost of combined power at the distribution network is 5.79 mills per kw-hr, a saving of 16% through combined energy generation. The incremental saving of 1.06 mills amounts to $2 120 000 annually on a 2 000 million kw-hr system.

Complementary Hydro-Systems.—The advantages of combining power sources of inherently different characteristics in one system are by no means limited to the large fuel-fed networks of the East. Although only a few have been built thus far, a number of opportunities exist for the complementary operation of base-load run-of-river and peak-load storage hydro-plants in the same system. Some of these complementary operations, however, are subject to the economic and operating disadvantages of connecting transmission lines more than 100 miles long to the mutual load center.

Power from low-head plants on Western rivers may be combined with peak-load hydro-power from high-head storage plants, and it appears of interest to study the cost of possible combined operation. Large sustained river flow would permit a high plant utilization factor at these low-head installations. Deficiencies in power output (which are ordinarily short but fairly severe) ranging from 10% to 50%, would usually occur during the summer flood period of reduced head and winter freezing periods of low water. During the winter low water, rated capacity would not be impaired, but operation at a plant factor less than 100% would become necessary.

Due to the low average head, the cost of power plant and machinery is relatively higher, and the cost of providing peaking capacity would be, therefore, greater than at higher head plants. The high utilization factor, and the large proportion of total cost required for power-plant building and machinery, appear to "earmark" these low-head river-run plants as natural base-load power producers. Operation on a 50% load factor, for instance, would require wastage of nearly one-half the power of the river otherwise within the plant capacity. Conversely, combined operation together with a peak-load storage plant would enable the fullest use of available power and greater earnings upon the larger unit investment necessary in the low-head plant. The function of the high-head plant would be to carry all peak load in excess of the low-head plant capacity and all seasonal capacity (winter) or energy (summer) deficiencies of the latter.

Example 3.—As an illustration of the advantages of combined use a study of possible combined high and low-head operation is presented herewith on the basis of the following data:



(*a*) Eastern Hydro-Steam System; Allocation of Hydro and Steam on Annual Load Curve (Diagram Represents 3 Kilowatts at 50% Load Factor). (*b*) High-Head and Low-Head Hydro; Allocation of Peak and Base Hydro on Annual Load Curve (Diagram Represents 1 Kilowatt at 50% Load Factor).

FIG. 33.—TYPICAL COMBINED LOAD-FACTOR DIAGRAM

Peak hydro use factor $= \dfrac{274}{0.4 \times 8\,760} = 7.8\%$

Peak hydro deficiency use factor $= \dfrac{195}{0.4 \times 8\,760} = 5.6\%$

Total peak hydro use factor $= 13.4\%$

Low-head hydro use factor $= \dfrac{3\,911}{0.6 \times 8\,760} = 74.4\%$

High-head plant: Peak + deficiency energy $= \dfrac{274 + 195}{8\,760 \times \frac{1}{2}} = 10.7\%$

Low-head plant: Base energy $= \dfrac{3\,911}{8\,760 \times \frac{1}{2}} = 89.3\%$

Total energy.................................. 100.0%

The following assumptions as to cost and operations are made:

(1) Low-head power-plant cost, $104 per installed kw with an installed cost of transmission and reception facilities at $30 per kw;

(2) High-head storage development with 1 700 kw-hr per kw-yr of available energy, at an installed cost of $60 per kw plus transmission and reception facilities at $30 per kw;

(3) Interest 3.5% and amortization through a 40-yr, 3.5% sinking fund; and

(4) Combined operation on a 50% load factor similar to Fig. 33(*b*).

Fig. 33(*b*) illustrates the complementary function of the peak-load storage hydro, both in carrying 40% of the combined annual peak load and in operating on base-load from storage during the winter period of low stream flow. The comparative cost of power at the distribution net is calculated at 1.81 mills (Item No. 22, Table 15(*b*)) for combined use as compared with 2.04 mills (Item No. 15) from the aforementioned low-head plant, a saving of 11% (Item No. 23). With an average annual output of 3 000 million kw-hr, the 0.23 mill saving would amount to $690 000 per yr.

Unused hydro-electric energy shown as the shaded area at the left in Fig. 33(*b*) might be utilized by raising the plant factor, either by developing a higher load factor or by combination with additional semi-peak generating capacity.

General Comments.—The combination of power sources of unlike characteristics, as described herein, so as to fit a system load shape best, represents (in common with load-factor increase through diversity in use) a mutual reduction in reserve capacity. This is one of the advantages of grouping power systems through inter-connections over natural market areas.

LEVERETT S. LYON,[47] ESQ. (by letter).—In their public aspects power and the costs of power are subjects of great consequence to economists. Mr. Uhl has given an excellent discussion of these costs. He has enumerated the important items, both fixed and direct, and has emphasized the significance of each. He has indicated that the engineer must not overlook them in analyzing projects—that if he does he changes from an engineer to a promoter.

---

[47] Executive Vice-Pres., The Brookings Inst., Washington, D. C.

Although it is impossible to overstate the importance of costs from the point of view of constructing projects, it is from another point of view that they become of great concern in public policy, and to economists. The economist's interest in cost, in engineering, and in any other matter, is essentially in terms of public policy in relation thereto. It is the failure to realize that the economist is concerned with public policy which transcends the limits or boundaries of any given industry, that causes many people to say that economists never agree. Such a position is untenable. It comes from confusing so-called economists with those who are what some like to refer to as professional economists. There is a difference between the farm economist, the labor economist, the business economist, the practical economist, and those who more truly represent the profession. The difference is that the latter type are interested in the nation's welfare rather than the welfare of any particular industry or group.

The professional economist is concerned with the question of how to use the nation's resources to the best advantage in the public interest. This means securing the largest possible output for the smallest input—a good engineering concept. In more detail, this means that if input can be had at a lower cost in one form than in another the lower cost form is the one to use.

Questions of cost thus viewed become questions of public policy and, therefore, of interest to the economist as costs find reflection in prices. In ordinary business, such as manufacturing or merchandising, or in any other competitive field, the costs of an individual company may have no direct relation to the prices at which it can sell its product. If there are five manufacturers of a given commodity for example, competing in a given market, and each has a cost that is different from the others, the one with the lowest cost will get as much of the business as he desires or can supply—unless the others sell below so-called "costs." It does the high-cost competitors no good to complain that their costs will not permit them to compete profitably. Prices simply are not made that way in competitive markets. In such a situation a high-cost manufacturer has no choice but to forget part of his costs, to close his eyes to the nicely worked-out "cost system" of his accountants, and to remember that competition came before accountants and will live long after them unless the nation becomes essentially socialistic.

In such a situation the manufacturer "closes his eyes" to some of his fixed charges. This is not difficult if his fixed charges are not bonds or other borrowed money on which there is a definite interest charge. If there is no such charge he will come to the conclusion that his investment is not worth as much as he thought it was—that it is indeed only worth what he can earn on it.

If he has a fixed charge in the form of bonds which leads to a foreclosure or a re-organization, his fixed charge after the re-organization will no longer be what it was before. By the ritual of a Court procedure or of a re-organization committee his costs will have been reduced. Accordingly, if he must think of his prices in terms of cost, all is now made easy. Although the original investment in the company has not been changed, the bookkeeping can now be changed so that "book costs" may now be in line with selling prices.

Of course, there is a limit below which prices will not be reduced even in a competitive market. In general, a manufacturer will hesitate to go below his direct charges although he may be quite willing to conclude that anything he can make above them is better than nothing. Many manufacturers find it profitable to go even below their direct charges at times in order "to keep in the game during a period of sharp recession." It may pay well to take a loss even on direct charges for a time with a view to being "in the picture when the situation is better."

The idea that, in all industry, prices should cover costs is persistent. The business man finds it difficult to escape from the feeling that "my investment is in this business, I am entitled to a return." This seems an entirely natural point of view. Indeed, it is a natural reaction to the situation, but there is an important idea of great social significance which opposes it. This idea is the one already stated, namely, that the resources of the nation should be used so as to give the greatest possible output at any given time for the smallest possible input. This really means that a buyer, whether he is a consumer buyer, or a business buyer, should be in a position to purchase, at any time, at as low a price as any one will offer at that time. A consumer who buys a hat should be able to purchase it at the lowest price for which any one is willing to make that kind of a hat. A power company should be able to buy its coal, its machinery, construction materials, and to borrow its money at as low a rate as any one at any given time is willing to furnish those things. No one has ever yet presented another plan so well calculated to make the resources of a nation at all times give the largest total yield to all the people as this plan of economic organization.

Alternative plans that have been presented have certain merits. Their fundamental weakness is that without such a measure as a competitive market gives, of what the price should really be, there is no satisfactory way of knowing what it should be. For example, to claim that prices should cover costs leads into the greatest difficulties. Whose costs, for example? On such a basis (that a manufacturer is entitled to his costs) there would be no incentive to keep costs down. Indeed, if he believes he should have a profit as a percentage of his cost, higher cost would be an advantage.

In the field of power, however, the competitive method of price determination will not apply. The reason is fundamentally the same as the reason in favor of competition in other fields. The people cannot afford to get along without competition in most fields; they cannot afford to have competition in this one. In other fields, without competition, goods cost too much. In the power field, with competition, goods cost too much. It has been discovered long ago that competition in the production of power for communities (and of many other commodities which are produced by so-called public utilities) will either result in building so much equipment that a charge based on costs will be higher than is necessary, or that the competitors will form a monopoly and charge an extortionate rate or that, in fear that competition will cut prices so low that the return on investment will be less than it would be in other fields, the desired facilities will not be built. In other words, in the field of power there is what economists call a "natural monopoly."

Since a monopoly cannot be trusted to create prices in the public interest, some social regulation of rates has been established in every State. A social regulation is directed primarily at the question of what price should be charged. Since the commissions which have been given this responsibility have no competitive tests they have groped, none too happily, in an effort to find a satisfactory method of relating costs to prices. This is not the time nor the place to describe the trials and tribulations that have beset the public utility commissions. Every one knows something of their struggles to determine what costs should mean—not in terms of expenses for building a project, but as a basis for rate-making. Shall they take all costs into account? Will all costs mean production costs? If so, production when? Will production mean original production costs or will it mean reproduction now? Or will it mean that beautiful but vague concept, cost on the basis of prudent investment?

All Mr. Uhl's observations on variables are relevant for consideration in trying to relate cost to prices. One good example is his comment on obsolescence. If one wishes to compute the cost of producing power as a basis for determining the prices at which it should be sold one would need to include a charge for obsolescence; but this, in turn, as Mr. Uhl has shown, depends upon the calculations which one makes as to how rapidly new equipment (even new inventions) may come into the field to supplant the old. Even if everything which the past tells is included, something new may happen. There may be an Edison, and coal may be made relatively obsolete in many communities. Gas may replace electricity. Some physicist may "pull" a power ray out of a laboratory which will make hydro-electric plants old-fashioned almost over-night.

What happened to the canals when the locomotive was invented is a matter of history. The struggles of the railroads and the Interstate Commerce Commission in an effort to find a rate for railroad traffic that will take care of the costs of the railroad companies is a problem of the present day. They are now at that nightmarish stage at which no one seems to know—even if they wish to cover all costs—whether it will be better to push the rates up or to push them down. "Verily, the way of the price fixer is hard" even when he does the fixing with the aid of the law.

Quite aside from these deeper issues, however, there are others which are of public importance when prices must be related to costs. It is always proper to ask whether the costs are fair or unfair. Are they really the necessary costs or are they "padded"? Is the enterprise capitalized at the minimum necessary to furnish the service or is it over-capitalized? Are officials over-paid or otherwise? To what extent are holding companies and similar financial and managerial mechanisms an effective means of organization and operating, and to what extent, if any, are they means of adding costs, positions, and salaries, on which rates are to be computed? Such questions should properly be asked and answered, not in an atmosphere of acrimony and controversy, but of careful consideration of the accounting, engineering, and economic issues involved.

It is the raising of such issues of costs as these which has introduced the now much discussed "yardstick" as a proposed method of determining what prices should be. Of course, the so-called "yardstick" is not a new idea. Every method that can be applied to determining what prices shall be—even competition—is a yardstick; but the great extension of Government operations as a means of comparing costs does offer, in size at least, something new. It also introduces new difficulties by the half-dozen if not by the score. To such problems as how to measure costs, reproduction costs, and the like, it introduces that most confusing of all cost concepts, joint costs. To illustrate: If a dam is built as a means of creating power and, at the same time, as a means of providing irrigation, and, at the same time, for purposes of flood control, and, at the same time, to lift a backward community into an industrial community, how much of the costs of the project—of each item of fixed costs—such as Mr. Uhl mentioned, should be charged against the cost of power?

Finally, Mr. Uhl's excellent paper refers to the contributions of the power industry to the American nation. As indicative of these contributions he cited the investment and the contribution through taxes which had come from this industry. These criteria of contribution are worthy of mention, but they do not do justice to the power industry. Although it is politically helpful to point out the tax payments of a public utility, its real contribution to the nation must be measured in quite different terms.

Man's effort, from the earliest recorded time, has been to increase the output which he can secure from his input in labor and toil. It is as the power industry has added to this output or lessened this input that its contribution has been made. Mankind has always had resources at his disposal. He has progressed on power—as he has been able to utilize natural forces to supplement or replace his own puny efforts. It must be in calculations of the additions—or, perhaps, better—the multiplications of Man's unaided power which have come through the power industry that one can best estimate what it has given to the world. It has added a series of problems, and some of them are difficult, and it has not been done without cost, but the credit balance for the power industry is an outstanding one.

John T. Madden,[48] Esq. (by letter).—One unfortunate circumstance in the economic life of this nation is the frequent necessity of attempting to settle important questions by steering a middle course between two evils. In order to avoid Scylla, or the evil of monopoly, on one hand, and Charybdis, or the evil of unrestrained competition, on the other hand, legislators pursue the middle course, and public utilities become a regulated monopoly. This middle course does not always mean "clear sailing." In avoiding twin evils, other vexing difficulties are often encountered. To shift metaphors, a veritable witch's broth has been brewed in this public utility stew, combining engineering, economics, finance, law, and politics, and there are some who say that too little of that important condiment—ethics—has been used.

---

[48] Dean, School of Commerce, Accounts, and Finance, New York Univ., and Director, Inst. of International Finance, New York, N. Y.

There is no doubt that an incalculable amount of economic waste could have been avoided if politics had been kept out. Better cooks would have left out the complexities, uncertainties, and paradoxes of the law. Sound principles of economics, combined with ethics, would have avoided such dishonest and shoddy financing as there was. The engineering contribution seems to have been sound; at least, there is little condemnation on this score. However, although perfection in this area of human activity seems as unattainable as in others, on the whole, the results are fairly satisfactory; accomplishment is not as poor as some have alleged.

The story of this industry is the same old tale of industrial development in the United States, and it follows the usual pattern. A new industry produces a service which later comes to be regarded as essential. Progress is slow at the outset, proceeding in lame and halting fashion. For a time the venture is highly speculative, but, nevertheless, it manages to attract to itself the capital, skill, and energy of those venturesome souls always present in an acquisitive society. The industry reaches its "adolescent" period, making the customary errors of youth. Ultimately, it attracts the attention of politics and the law steps in. Controversies arise, and instead of resolving them with the aid of ethics and economics in simple and direct fashion, differences increase. The penalty for economic success is to have one's "head chopped off" in appropriate "Alice in Wonderland" style.

Despite the controversy and criticism of regulation and rate-making, the summary data in Table 12 are most impressive. The wonder really is that such progress could have been made in view of all the difficulties placed in the path of the electric light and power industry. Mr. Uhl concludes his paper with the statement that the "power industry is of increasing importance to the welfare of the nation and has made tremendous contributions to its wealth and income." This is a temperate statement, appropriate and becoming in the engineer. The record of progress from 1912 to 1936 is merely indicative of the potential capacity of the industry to contribute to the future wealth, income, and social betterment of the nation, if legitimate expansion could proceed. In fact, the record cited serves to "highlight" the serious damage to the national economy and welfare wrought by those who have used the industry as a political football. Mr. Uhl did not stress the fact that the power industry is a most important arm of the national defense, and those whose aim is to wreck it, or whose actions impede its capacity to serve the nation in the event of war, will have much to answer for at the bar of public opinion.

This Symposium has demolished the pretensions of those who have supported the alleged value of "yardstick" rates established by public plants scattered about the nation. The variable factors are so many and so incapable of being reduced to a common denominator that any comparisons would be worthless.

In his discussion of rate theories,[49] Professor James C. Bonbright has stated that "whatever the proposed remedy, the disease to be cured is generally diagnosed as one caused by the focal infection of the fair value doctrine," which he characterizes as Court-made law. The writer does not subscribe to his view. Despite the criticism of the fair value doctrine, relatively few rate controversies have reached the Courts. The legislature imposed regulation; and, to continue the medical metaphor, the regulatory "treatment" was to be administered to "patients" or "cases," no two of which, as shown by this Engineering Symposium, are alike biologically, chemically, or physically. While the legislature developed its "science of medicine," it was left to the commissions and the Courts to practice "the art of healing." There is a vast difference between the science of medicine and the art of healing. In this Symposium, the engineers who have studied the cost of power generation have shown that, although there is a certain general uniformity in the "anatomy" of physical plants, they vary considerably. The economist knows that the investment costs—"the flesh and glands"—vary far more than the "anatomy." In establishing the fair value doctrine, the Court left leeway for varying and individualistic treatment of the "patients." The physician who prescribes only one remedy for all his patients does not command much respect.

---

[49] "The Valuation of Property," by James C. Bonbright, McGraw-Hill, 1937, Vol. II, Chapter XX, p. 1079.

Proficiency in the art of regulation has improved greatly, just as the art of healing has shown great advance. Despite the "focal infection" which Professor Bonbright finds, the pragmatic test of the Court-made law reveals that the "patient" got along fairly well, although alternative treatment was not employed. The "doctor's" expenses, such as appraisals, legal and engineering services, and Court costs, were not unduly expensive considering the financial circumstances of the "patient." Furthermore, before 1932, this growing industry had made significant advances in its engineering technique; it extended the benefits of its service to countless hamlets and many thousands of persons who have not even yet had the benefits of railway service; it raised at reasonable cost all the capital required for its development; the cost of that service was greatly reduced; and, a sound basis has been laid for still further progress if the politicians will cease harassing the industry. Abuses have existed, of course; "write-ups" and "write-downs" have occurred on the books, but despite the allegations of watered capitalization, so commonly made, the fact is that no one knows either the prudent investment cost or the fair value of the existing plant, and no one will know until an inventory and an appraisal are made.

Economists would find it difficult to point to any other business institution that has made such forward advance in so short a period, with equally beneficial social consequences. In fact, if social engineering were half as proficient as civil, electrical, and mechanical engineering have been, there would be no power issue of any consequence to-day.

Whatever may be the outcome of the prudent investment or fair value doctrines, or whatever may be the outcome of "yardsticks" and "big sticks," more attention is to be given to the preparation and maintenance of continuing fixed property records. Engineers will devote more attention to, and perfect, their techniques in measuring the effect upon fixed property of the several causes of depreciation. Assume that the engineers accomplish all that is to be desired in these matters; assume that a technique for measuring the extent of wear and tear has been developed with reasonable accuracy; and, assume that engineering experts develop a foresightedness as to obsolescence—there is still one more question to be answered. Is the object of the business struggle to preserve intact the mere dollar capital invested, or shall it be to protect the "real" invested capital in terms of purchasing power? The distinction is important and this problem is no less baffling than other problems connected with this difficult question. The gyrations of price levels in the United States since the World War vitally affect the accounting process, which attempts to record financial facts in terms of a variable "yardstick." It will be observed that the computation of depreciation under either the fair value principle or the prudent investment principle does not touch upon this point, particularly if by the latter principle is understood that, in so far as depreciation is concerned, the sum to be charged to operating expenses is the proportion of mere dollar investment that is to be amortized.

Recent experience bears out the suggestion of Mr. Scharff that in competitive industry it will be necessary or desirable to have a more accurate determination of the monetary sums to be set out in the accounts for the various causes of depreciation. In too many instances the depression beginning in 1929 revealed an impairment of dollar capital through neglect in this respect.

There is another cause of depreciation beside those commonly mentioned in discussions on the subject; namely, shifting in population, or shifting of industries, which may completely alter the character and extent of a company's business, and increase its obsolescence factor. The perfection of air-conditioning may have a serious effect upon the popularity of seaside resorts in the summer. There still remains much work to be done in a more accurate study of the market, and the results of such a study might indicate an increase or decrease in the provision for obsolescence. Apparently, Mr. Scharff recognizes the difficulty of shifting the loss due to obsolescence; it may be placed upon the present generation of rate payers, upon a later generation; or it may fall upon the owners of the enterprise. In some cases it may be shifted to employees who will accept reduced wages to compensate for the loss to an employer who finds himself in an unfavorable competitive position with other manufacturers with more modern equipment.

In 1906, Woodrow Wilson stated that the automobile would be responsible for an increase in socialism since the vulgar display of the wealth of those who owned automobiles would create dissatisfaction. Although this fear proved groundless, the automobile did injure the revenues of railroads and electric railways. This Symposium displays no present fear on the part of engineers that radical changes in the art are in prospect. One can easily dream of a revolution that would jeopardize the entire investment in electrical properties. Stranger things have happened. If more extensive public ownership is to come eventually, the loss would then fall upon taxpayers. Perhaps taxpayers should think more than once before they rush heedlessly into Government ownership.

Briefly, then, it appears that engineering science has so definitely established comparative costs and uses of hydro and steam projects that Government and finance should be governed by these conclusions. Further progress in engineering studies on depreciation and obsolescence will determine the final disposition of this vexing question, but the writer concludes that, in the future, greater allowances should be made for this item of fixed cost. It now appears that too much of the burden is likely to be shifted to the investor, whereas, in all good conscience, a substantial portion should fall upon the consumer.

The interest problem comes down to this: Either Government development and ownership with its lower rates, or private development with interest rates fixed under the usual market conditions. As for taxes, the burden is shifted either to suppliers of the things the companies buy, to their customers, or to the investors; but when the average tax burden of the industry is 15% of the revenue, and higher in some instances, it becomes an extremely important matter. Unquestionably, it must go into costs, but the important question is whether it is to be recovered from the consumer or from the investor. If an attempt is made to recover so much from the investor that the rate of his return is lowered, he will transfer his attention to other investments and the capital needed for development will not be forthcoming.

The problem of joint costs is insoluble, and it is the same as that faced by the Australian sheep raiser who sells mutton, pelts for ladies' coats, and wool.

Incidentally, the comparisons made with foreign countries are of little validity in the present case. The social and economic milieu abroad, particularly, and the legal philosophy are so different that little is gained from their experience in solving problems in the United States.

If, as some believe, the nation is on the threshold of an era of decentralization, any prophecy of the social and economic consequences is futile; but it does suggest this: It would seem that proposals to establish, under Government ownership, various large units scattered throughout the nation as "yardsticks" is untimely, because it appears to commit the Government to a wasteful economic venture at the "tail end" or closing phase of engineering development. Certainly, if decentralization is to be the significant operating practice in the future, the Government should hesitate in the establishment of "seven little sisters" to the TVA.

Regulation in itself is an adequate instrument for social or economic problems. In fact, it is the best instrument possible, if used properly. With equal facility, one can either shave himself or cut his throat with a razor; it all depends upon the way one uses the instrument. Even in those cases where qualified economists, or capable engineers, sat on commisions, they found themselves confronted with political problems rather than ethical or economic ones. Many serious controversies have grown out of the abuse, and not the use, of regulation.

R. L. THOMAS,[50] ESQ. (by letter).—It is significant to the writer that Mr. Scharff, in referring to a 25-yr old report[21] on depreciation, selects as one statement with which there is still general agreement the comment that "perhaps there is no single subject in connection with valuation that has caused more trouble than depreciation." There seems to be something inherently controversial in the subject—something that causes blood pressures as well as voices to be raised. There is no subject on which it is more difficult to keep discussion within reasonable bounds—no subject so surrounded and obscured by "fog and smoke." Using another metaphor, the Hon. Clyde L. Seavey, Acting Chairman of the Federal Power Commission, in an address before the American Bar Association in August, 1936,[51] aptly referred to the "inferno of depreciation."

---

[50] Project Engr., Safe Harbor Water Power Corporation, Baltimore, Md.

Engineers, more than any other class, should be striving to cut through the "haze"—to find a way out of the "inferno." They should bend their efforts toward simplifying rate-making procedure in the public utility field, provided that such simplification does no injustice to either the rate-payer or the utility.

Mr. Scharff has done a real service in emphasizing the need for consistency between determination of depreciation for valuation and rate-base purposes and annual depreciation expense. His proposal that the actual depreciation be determined annually by mathematical formulas, with periodic checks by field inspection and engineering investigation, is theoretically desirable and is a logical method if it is necessary to use a depreciated rate base. Its practical application, however, is another matter. Even in the case of the simplest of the causes of depreciation—physical deterioration—the writer regretfully doubts that it will be possible to obtain general agreement on a series of "objective measurements" which will be recognized as measuring the extent of physical deterioration. With respect to the other causes, it seems even more likely that determination of the extent of depreciation will remain a matter of judgment. As a matter of fact, there are many cases in which it is impracticable to distinguish between several of the causes.

Now, there are undoubtedly many cases where there is no other "way out," and it is necessary to make the best possible determination of depreciation by a combination of "objective measurements," investigation, and judgment. A better way out of the "fog," when it is feasible, is the use of an undepreciated rate base. The complete sentence in Mr. Seavey's address[51] is: "And, in order to escape as far as possible from the inferno of depreciation, the California Commission used an undepreciated rate base with a correlative adjustment in expense."

Undoubtedly, the "correlative adjustment in expense" refers to the sinking-fund method of depreciation accounting which has been used in California for a long time. Under this method the total annual accretion to the depreciation reserve consists of two components—one the annuity which is chargeable to the rate-payers as an operating expense, and the other the interest on the reserve, which is not chargeable to the rate-payers, but is a deduction from income. It is not necessary to know the "actual" depreciation. The annuity, as Mr. Scharff states in his reference to special cases, equalizes the annual depreciation expense over a long period of years.

Five years of intimate knowledge of the use of the method at a large hydroelectric project has convinced the writer that the statement often made, that the method is complicated, is entirely unfounded. As compared with an annual or even a periodic determination of actual depreciation it is extremely simple.

---

[51] *Public Utilities Fortnightly,* October 8, 1936, p. 546.

Another method of using an undepreciated rate base is to determine the depreciation expense charged to the rate-payers by some simple and more or less arbitrary, but fair, method and credit the rate-payers with interest on the accumulated depreciation reserve at an arbitrary interest rate. This is the method used in the District of Columbia under the Consent Decree of the Supreme Court of the District of Columbia.

An objection sometimes made to the undepreciated rate base is that it is contrary to "accepted law." This statement was made recently by a well-known engineer before a Public Service Commission; yet it is common practice for electric utilities, including the company with which the aforementioned engineer is connected, to establish, among themselves and with large customers, annual payments for the use of facilities (as, for example, in interchange) by applying a fixed percentage to a constant sum of money. The rate base and the payment go on year after year without deduction for depreciation. Without attempting to argue the legal questions, the writer believes that if the method is equitable it will be found to be legal "in the long run."

THEODORE B. PARKER,[52] M. AM. SOC. C. E. (by letter).—In his paper on "Cost of Hydro-Generated Energy," Professor Barrows has developed a very effective method of analyzing such costs, and has tabulated cost data relative to a great variety of representative plants. Hydro-electric developments differ so widely in their general design, and must conform so frequently to special requirements, that it has been considered a difficult task to secure a common basis for comparison of costs. It is interesting, therefore, to find that Professor Barrows has managed to reduce a considerable number of variables to what appears to be a common denominator.

His method appears admirably adapted for making general comparisons of different plants. For a detailed study of a given power system it is naturally more accurate to use the actual characteristics of the system and its parts; that is, to determine the comparative costs of two alternative schemes for supplying equivalent generating capacity, the most reliable method is to compute the total system cost under each plan. "Short-cuts" or approximations are frequently misleading.

One of Professor Barrows' conclusions is that, "although, in general, the cost per kilowatt-hour tends to lessen as head increases and to lessen with the size of the plant, the effect of capacity factor is more predominant" (see heading, "Cost of Water-Power Output: Effect of Head, Capacity, and Capacity Factor upon Cost"). This statement can scarcely be disputed. On the other hand, the economy of high-head plants is sometimes more apparent than real. Plants with heads greater than 400 ft (with the exception of Boulder Dam and similar recent developments) generally require the use of long conduits. These conduits are frequently wood pipes or flumes which depreciate rapidly and require considerable maintenance. Where more permanent materials are used, there is still a greater proportional annual expense than for plants with the power-house directly at the dam. This tends to render incorrect a comparison of such plants based on the same fixed charges.

---

[52] Chf. Engr., TVA, Knoxville, Tenn.

At a high-head plant the waterway frequently represents a large proportion of the investment. Its capacity must equal the capacity of the plant, with only minor allowance for load factor. Increment cost at such a plant, therefore, is high, and may affect the lower cost of generating equipment. For certain purposes it may be found more economical to secure additional peak capacity at the low-head plants of a system, for which the energy cost may be high but the capacity increment cost low.

In Table 6 Professor Barrows includes certain high-head plants numbered 31 to 39, inclusive. These are comparatively small developments in Utah which were constructed prior to 1912 by various local interests, and, later, taken over by the Utah Power and Light Company. They were built at a time when the general cost level was lower than at present. The waterways are mostly of wood, and have required extensive maintenance and replacement which are apparently not reflected in the annual costs given in Table 6. Cost data from this group, therefore, are not a very reliable basis for appraising present-day, large-scale developments.

A study of Table 6 and the supporting text is most interesting and serves again to emphasize the fact that where exceptional economy is secured the cause is frequently some special condition rather than any general relation of head and flow. For example, the Chelan Project (Plant No. 43) owes its value largely to an opportunity to raise the level of a large lake by means of a relatively short dam at its outlet.

The effect of capacity variation is shown clearly in the case of the Rock Island Development (Plant No. 49), on the Columbia River. For the four present units the total cost is given as $14 555 000 and the unit energy cost as 0.40 cent per kw-hr. Since six additional units can be added at a cost not much exceeding $1 000 000 each, it is apparent that this will greatly reduce the cost per kilowatt-hour. Owing to the unusually well sustained flow there would be a large increase in total energy, but naturally not in proportion to installed capacity.

Table 6 shows a considerable number of reasonably large modern projects which develop energy at what might be regarded as high unit cost. This, it is assumed, must be justified by favorable load factors, high cost of power from other sources, or other local conditions. In general, it has been the writer's experience that outside of special conditions, such as existing lakes and unusually favorable topography, the most effective factor in securing economy is a high ratio between low flow and length of dam. Such a condition allows the most effective use of the structures built, and the greatest return on the investment.

In recent years, low-cost hydro-energy production has been obtained at developments where there are large, well-sustained stream flows, and where the power houses are directly at the dams. This is a most important factor in the very low costs obtainable at the large Federal developments on the Columbia River. It is a smaller, but still an important, factor in the relatively low costs at the plants on the Susquehanna River where the flow is large but not so well sustained. Many of the successful Canadian developments are situated on rivers having a large volume, with flow sustained by natural lakes on their head-waters.

Where long conduits are used there is a definite limit to the economy possible, except where a large drop can be obtained in a relatively short distance. This sometimes occurs where there is an opportunity to tunnel through a divide or to effect some similar short cut. To secure low cost per kilowatt-hour with long conduits, it is necessary to have a high capacity factor—that is, a high rate of use of the facilities provided.

In a given power system it is frequently desirable to determine where the cheapest generating capacity can be obtained; that is, to determine which plant can best be over-developed for use on the peak of the load. Other conditions being favorable, the lowest incremental cost is frequently found at a plant with moderately high head, but with the power house directly at the dam.

The most vital consideration affecting hydro-electric costs is the rate at which fixed charges are computed. Professor Barrows has taken fixed charges on the Federal hydro-electric projects at 6.5%, whereas the others are on a 10% basis. Of the fixed charges the largest factor is the interest rate, which varies with economic conditions and with the agencies involved. During recent years considerable Government financing has been effected for less than 3 per cent.

Depreciation (that is, purely physical depreciation) varies greatly with the type of development. Where most of the investment is in structures and equipment of limited life, the total average depreciation may exceed the 2% maximum rate given by Professor Barrows. On the other hand, there are certain types of development in which a large part of the investment is in items having practically no physical depreciation. An example of such items is the investment in reservoir facilities, consisting of cost of land, clearing operations, reconstruction of railroads and highways, and back-water protection.

In addition to the tabulation of cost data for fifty-seven hydro-electric developments, a summary is given of estimated costs for several of the larger Federal projects recently completed or under construction. Included among these is a summary of estimated costs for eleven existing or proposed major projects of the Tennessee Valley Authority.

Unit energy costs are given for two conditions: (1) Those based on power development cost alone, given as $135 000 000; and (2) those based on total cost, given as $520 000 000. Fixed charges are taken in each case at 6.5 per cent. The resulting unit costs are given as 0.183 cent and 0.60 cent per kw-hr, respectively. It is thus inferred that the cost of energy to the TVA lies between these limits.

The actual cost of energy to the TVA depends upon a number of factors, not all of which can be discussed adequately herein. It seems appropriate, however, to emphasize several factors. The actual interest rates paid by the Government during the TVA construction period have been very low. These rates are a matter of official record and can be verified easily. The physical depreciation of the TVA projects as a whole will be extremely low. More than one-third of the cost is in the reservoirs, with negligible depreciation, and much of the remainder is invested in massive structures of concrete and earth. The estimated annual depreciation of the dams, reservoirs, and generating stations (excluding transmission lines) will be less than 1% of the total cost.

Among the eleven projects listed as costing $520 000 000 is the Gilbertsville Project, which, if built, would be utilized mainly for flood control. Its estimated cost is more than $110 000 000, which provides for only a moderate generating capacity. This can scarcely be classed primarily as a power development, and no theory of allocation would justify charging any considerable part of the total cost of this development to power. With Gilbertsville excluded, it is apparent that the upper limit of 0.60 cent per kw-hr would be reduced considerably even on the basis of 6.5% fixed charges. The effect of reducing the rate of fixed charges is obvious.

When final costs are available and definite allocations have been made, it should prove very interesting to analyze the TVA and other recent Government developments, and to compare them with the projects listed in Table 6. Meanwhile, the writer wishes to congratulate Professor Barrows on having developed a method which makes such comparisons practicable.

Philip Sporn,[53] M. Am. Soc. C. E. (by letter).—The question of true production economics is one to which engineers must pay more and more attention if more goods are to be available for distribution. Although the production of electric power and electric service has been developed to an unusual degree on sound technical and economic lines, the subject will bear further study and analysis. There have been periods in the past when the power business was growing at such a rate that almost the entire effort had to be centered upon the task of meeting demands. In such periods some mistakes—particularly economic mistakes—may have been made, but these did not show up and their cost was quickly absorbed in the growth of the business; but, as business approaches technical and economic maturity, the cost of such even rare mistakes is more apparent and it becomes necessary to scrutinize more closely the economic merits of what is done in the way of building new capacity. Although Mr. Whitman's paper traverses familiar ground, it may well be that the very repetition of these principles will "bring home," not only to engineers but to others who are or who may become associated with, or who are in contact with, the power business, the need for careful economic analysis in any power situation.

This subject of the cost of combined energy generation is one that requires, above all, careful analysis. So much has been said and written on the subject of steam *versus* hydro energy (with prejudice substituted for facts and figures), that fundamentals are being overlooked in the desire to "make out a good case" for whichever side its author has chosen.

In reviewing the elements entering into the cost of energy as enumerated by Mr. Whitman, the writer is impressed by the fact that not enough emphasis has been placed upon cost of transmission and its effect on the cost of the delivered energy. After all, that, and not the bus-bar cost at the generating station, is the item of greatest interest. Those who have studied the problem closely and thoroughly understand the economics of power supply have been, for the most part, unable to find any sound economical basis for long-distance transmission of power.[54] In general, energy is most economical when generated nearest the load. Beyond a certain distance, transmission definitely is not an economical proposition; and, only too often, hydro developments require some long transmission to reach the load. Long-distance transmission of electric energy had its early development in areas where fuel was scarce and costly and there was available hydro power which could be developed cheaply. The early days of the electric power development in California are a case in point. However, even there, this situation has changed with the discovery of oil and gas supplies near the load. The writer feels that this question of transmission cost is very definitely a limiting factor in the development of large hydro-electric projects. Therefore, when a question arises as to whether a hydro-plant or a steam plant should be built to meet the growth of load, one should be very careful not to overlook the cost of transmission.

---

[53] Vice-Pres. in Chg. of Eng., Am. Gas & Elec. Service Corp., New York, N. Y.

In illustrating the economic principles of selecting the source of power, Mr. Whitman chooses the well-known situation at the Conowingo Plant, on the Susquehanna River. He could not have picked a better one. Everything was in favor of fitting that plant into the load curve economically: (1) Short transmission distance (only about 60 miles) to a large load center; (2) access to a large metropolitan load, rapidly growing, in which fuel costs were relatively high; and (3) an existing steam system in which there was sufficient steam-plant capacity to firm the larger part of the Conowingo capacity. One wonders how the Conowingo Plant, if proposed to-day, would appear in the light of the latest developments in steam-plant design. Mr. Whitman states that a new steam plant was estimated at that time to cost $135 per kw. The most pessimistic engineer, to-day, would expect to reduce this cost by at least $25 per kw, and if he were in an optimistic mood, by as much as $45 per kw. Mr. Whitman does not state what efficiency was estimated for the plant, but certainly the efficiencies (that is, the fuel consumption) estimated in that day for the new plant were not as good as those that would be estimated to-day with all the new knowledge of high-pressure and high-temperature operations. In 1925, engineers were thinking of plants with a fuel consumption of 13 500 Btu per kw-hr. To-day, 10 000 Btu per kw-hr is "within sight."

This leads to another thought. The common impression is that hydro-plants never wear out and, once built, are useful for all time. Granted that hydro-plants and equipment show the effects of wear and tear slowly, one still must not overlook the influence of obsolescence on these plants, an effect that has been accelerated in the ten years since 1928 by the very great improvements in generation of energy by steam. All those conversant with the facts admit freely that the great improvements in the art of generation of energy by steam have made the development of new hydro-plants less attractive; but it is often forgotten that the same advance in steam generation has made present hydro-plants less of a bargain than they appeared to be when built.

Of course, the plants are built, the money has been spent, and they will continue to be operated until their cost becomes prohibitive in relation to some new future developments. The writer wishes to emphasize this point on obsolescence to show that it may be a much more important factor in the determination of the economic value of hydro-plants than is generally assumed. However, he does not wish to be misunderstood in regard to hydro-electric power development. He has no prejudice against it; nothing but a desire to examine the facts clearly. The American Gas and Electric Company has in operation about 125 000 kw of hydro-electric capacity fitted into what is basically a steam system, with about 850 000 kw of installed steam capacity.

---

[54] *Proceedings*, Am. Soc. C. E., December, 1937, p. 1929.

The writer would like, also, to mention the subject of Federal hydro-projects which Mr. Whitman covers in the closing paragraphs of his paper. In concentrating on engineering calculations, one should not lose sight of some of the social implications in the development of large hydro-plants by the Federal Government. As indicated in the principles and data presented by Mr. Whitman, hydro developments are generally feasible, economically, only when they are made complementary to steam developments. To make them directly competitive, some form of subsidy is necessary and, if this subsidy is made by the National Government, the national economy cannot help but suffer. Moreover, a subsidy that brings this about definitely tends to reduce the national pay-roll.

Although it is well known to most engineers connected with the development of power, it is not generally appreciated that in a hydro-electric project, the principal cost of the energy is the fixed charges. Very little will go into operating expenses in the form of labor and materials.[55] In a steam-generating plant, on the contrary, fully 50% of the total cost of power goes into continuously recurring expenses for material, fuel, and labor. It has been estimated that for every billion kilowatt-hours generated each year by hydro, there is less paid out for labor and material by the approximate sum of $2 300 000. This amount is obviously reflected in further reduction in purchasing power and pay-rolls through the well-known downward spiral, so that it is entirely probable that this process results in as much as $10 000 000 to $15 000 000 of annual decrease in the national pay-roll for every billion kilowatt-hours of hydro-electric energy generated. Taking, as a fair assumption, the maximum possible hydro-energy that might be developed by subsidy along these lines at 20 000 000 000 kw-hr per yr, it can be seen that the production of such an amount of energy would mean a reduction in the annual pay-roll of between $200 000 000 and $300 000 000. This most certainly is not a negligible item in the national economy; particularly, since it will result in more expensive power to every one and the only beneficiaries of the development along these lines will be those who will be provided with additional means and outlets for investments of their capital in tax-exempt Government securities.

L. N. McClellan,[56] Esq. (by letter).—The cost of power developed in connection with the large multi-purpose projects that have been undertaken in recent years by the Federal Government depends upon two important factors: (1) The extent to which the cost of these projects is allocated to purposes other than power, such as flood control, improvement of navigation, conservation of water for irrigation and domestic uses, etc.; and (2) the period of time required to absorb the full power output. These facts have been stated by Professor Barrows and Mr. Page.

---

[55] *Proceedings*, Am. Soc. C. E., December, 1937, p. 1927.

[56] Chf. Elec. Engr., U. S. Bureau of Reclamation, Denver, Colo.

Congress recognized the flood control benefits of the Boulder Canyon Project and allocated $25 000 000 of the cost of the project to flood control to be repaid out of 62.5% of revenues in excess of those required to amortize the remainder of the cost of the project. The other 37.5% of the excess revenues is to be paid to the States of Arizona and Nevada in lieu of taxes. The Boulder Canyon Project Act provides that all funds advanced for the construction of the project are to be repaid in 50 yr with interest at 4% per annum. All Boulder Canyon power has been contracted for and the power contracts provide a definite date for each power contractor to start taking power and each contractor has a 3-yr period in which to absorb the full amount for which he has contracted. Therefore, this project is on a definite basis as to the allocation of cost and period required to market the power. The estimated cost of the Boulder Canyon Project, with full installation of generating equipment, is $143 000 000, including interest during construction. The estimated annual cost of the Boulder Canyon Project is given in Table 16 (Item No. 1), assuming that amortization of the $25 000 000 allocated to flood control is included in the rate base.

TABLE 16.—ESTIMATED ANNUAL COST OF BOULDER CANYON PROJECT

Item No.	Assuming that the amortization of the $25 000 000 allocated to flood control is:	Interest rate, percentage (1)	COST, IN THOUSANDS OF DOLLARS				
			Interest and amortization (2)	Depreciation (3)	Operation and maintenance (4)	Payments to Arizona and Nevada* (5)	Total annual cost (6)
1	Included in the rate base.........	4.655	6 657	802	841	700	9 000
2	Not included in the rate base.....	4.263	5 030	880	841	700	7 451

* In lieu of taxes.

Revenue from stored waters will average about $250 000 per yr, and that from secondary energy will average $350 000 per yr, assuming that the present rate of 0.5 mill per kw-hr for secondary energy remains unchanged. Deducting these sums from the total annual cost leaves $8 400 000 as the annual cost chargeable to firm energy. The average annual output of firm energy during the 50-yr amortization period will be 4 120 million kw-hr, and the average cost of firm energy will be 2.04 mills per kw-hr delivered at the high-voltage bus at Boulder Power Plant. The present rate for use of falling water for generation of firm energy is 1.63 mills per kw-hr, in addition to which the power contractors are required to repay the cost of the generating equipment and to bear the cost of the operation and maintenance of the power plant. At 55% load factor these additional costs amount to about 0.57 mill per kw-hr making the total cost of power under the present contracts about 2.2 mills per kw-hr.

There has been considerable agitation on the part of the contractors for Boulder power to have the interest rate reduced from 4% to 3.5%, which they contend would be more in line with the present rate of interest paid by the Federal Treasury on borrowed money, and to defer repayment of the $25 000 000 allocated to flood control until the remainder of the cost of the project has been repaid. These changes would require additional legislation and if they were made the annual costs would be reduced as indicated in Item No. 2, Table 16.

Deducting the revenues from stored water and secondary energy amounting to $600 000 per yr from the total annual cost of $7 451 000, would leave $6 851 000 as the cost of firm energy. On this basis the cost of firm energy would be 1.66 mills per kw-hr delivered at the high-voltage bus at Boulder Power Plant. This corresponds with 1.7 mills per kw-hr reported by Professor Barrows for the cost of Boulder Canyon energy. Reducing the rate of interest from 4% to 3.5% per annum and eliminating the $25 000 000 allocated to flood control from the power rate base would reduce the cost of firm energy delivered at the high-voltage bus at Boulder Power Plant about 18.6 per cent.

The Grand Coulee Project on the Columbia River in Eastern Washington is the largest of the multi-purpose Federal projects. It will make available almost twice as much firm energy as the Boulder Canyon Project and no part of this power has been contracted for to date (July, 1938). The project is a combination irrigation and power development, and power revenues are expected to repay a large part of the cost of the irrigation development as well as the entire cost of the power development.

The Grand Coulee Dam and Reservoir will serve both irrigation and power and, because of this dual purpose, it has been tentatively proposed to allocate one-half the cost of the dam and reservoir to irrigation and one-half to power. The total estimated cost of the project is $425 000 000. Of this sum, $282 000 000 is the cost of the irrigation development which is to be repaid in 40 yr without interest (conforming with the established plan of repayment of Federal Reclamation projects), and $143 000 000 is the cost of the power development which is to be repaid in 40 yr with interest at 3.5% per annum. It is estimated that the water users will be able to repay about $23 000 000 of the construction cost of the irrigation development in addition to the cost of operation and maintenance, leaving about $243 000 000 of the cost of the irrigation development to be repaid out of power revenues.

With the 5 000 000 acre-ft of active storage in the Columbia River Reservoir, the firm energy output of the Grand Coulee Power Plant will amount to 8 138 million kw-hr per yr. A considerable period of time will be required for the market within economic transmission distance to absorb this large amount of energy and for the purpose of determining the cost of power it is assumed that about 20 yr will be required to market all the firm energy. It is believed that this is conservative, and it is expected that the full output will be absorbed in a considerably shorter period. If so, the deficits in the early years and the cost of power will be reduced somewhat. In addition to the firm energy there will be large amounts of seasonal or secondary energy which it is proposed to use largely for pumping water for irrigating the lands of the Columbia Basin Project. It is assumed that the water users will pay 0.5 mill per kw-hr for secondary energy used for pumping purposes.

An analysis of the financial operation of the Grand Coulee Project is shown graphically in Fig. 34, which is based on the assumptions that the firm energy will be absorbed at the rate of 720 million kw-hr during the first year of operation, increasing at the rate of 360 million kw-hr per yr until the twenty-second year when the annual output will be 8 138 million kw-hr. The irrigation development will be 50 000 acres in the first year and will increase at the rate of 50 000 acres per yr until the total of 1 200 000 acres has been developed.

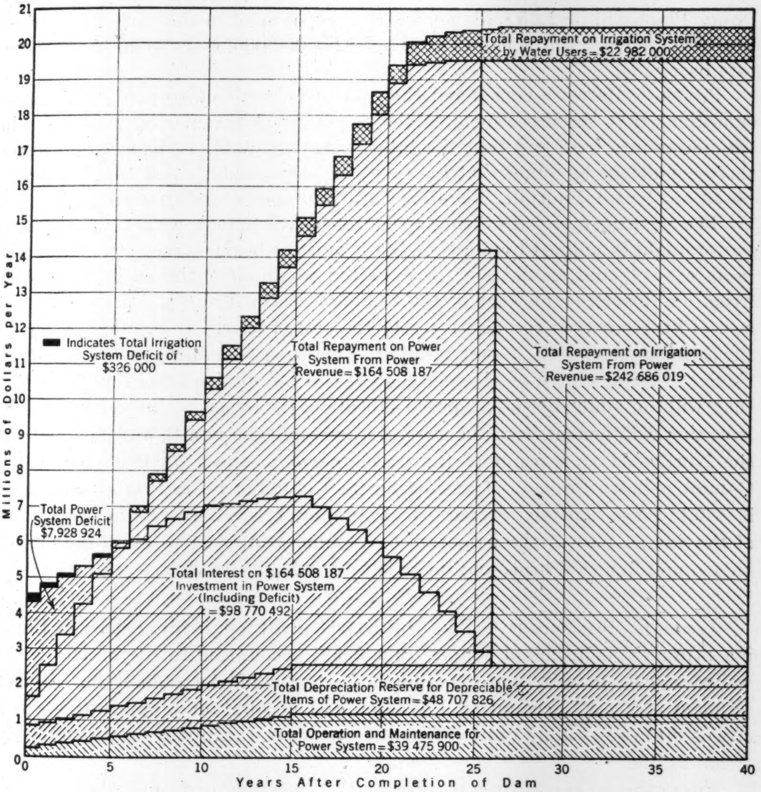


FIG. 34.—POWER DEVELOPMENT, COLUMBIA BASIN PROJECT

Interest is computed at 3.5% per annum on the power system investment and no interest is charged against the irrigation system. Fig. 34 indicates that during the first five years of operation the revenues will be insufficient to meet the annual interest charges on the investment in the power development, and deficits amounting to about $8 000 000 will accumulate which will have to be paid off with interest in subsequent years, adding to the cost of power.

Interest payments will reach a maximum in the sixteenth year, after which they will reduce rapidly as the investment in the power development is amortized. The cost of the power development will be amortized in 26 yr and the cost allocated to irrigation will be repaid in about 41 yr. This study indicates that the cost of firm energy delivered at the high-voltage bus at Grand Coulee Power Plant will be 2.25 mills per kw-hr if repayment of the cost of the irrigation development, to the extent of about $243 000 000, is included in the power rate base.

Professor Barrows considered the cost of Grand Coulee power on the assumptions that the investment in the power development only is included in the power rate base and that the total energy available is disposed of; under these conditions he found that the cost of energy would be 1.5 mills per kw-hr based on the total output, including both firm and secondary energy.

The propriety of subsidizing irrigation development with revenues from power might be subject to question, but it must be borne in mind that the water users cannot, and should not, be expected to shoulder the entire cost of an irrigation development, such as the Columbia Basin Project. If the proposed cost of firm energy is competitive with the cost of energy from other sources in the Northwest and the power users are able to secure power from the Grand Coulee Dam as cheap or cheaper than it can be obtained from other sources they will not suffer by the proposed subsidy of the irrigation development. In fact, they will benefit from the general increase in the wealth and commerce of the Northwest as a result of the development of the 1 200 000 acres of the Columbia Basin Project. Considering the Columbia Basin Project as a whole it would seem entirely proper to apply power revenues to the repayment of the cost of part of the irrigation development in order to place the project on a sound financial basis and make it economically feasible.

James C. Bonbright,[57] Esq. (by letter).—Although Mr. Scharff is thinking primarily in terms of proper "financial" accounting for depreciation, the writer wishes to add some comments in terms of the related but distinct problem of "cost" accounting. What a cost accountant properly treats as a cost is often something quite different from what a company auditor properly treats as one.

First, the writer wishes to discuss the question why any allowance for depreciation need be made in estimating, say, the average kilowatt-hour cost of generation by a given steam plant at 60% load factor. Presumably, the answer is that the economic life expectancy of the plant assets must be prophesied in order to determine the total number of units of energy against which the initial cost of constructing the plant must be charged. If a new turbine were required for each kilowatt-hour of energy to be produced, no allowance for depreciation would be needed. The entire cost of the turbine would then be charged directly to each kilowatt-hour, with the result that electricity would be prohibitive except for experimental purposes. On the other hand, if the turbine and its parts were indestructible, no depreciation allowance would be required, and the entire fixed charges on that asset would be limited to interest and taxes. In fact, however, neither of these extremes will be realized. The turbine will have, say, twenty years of useful life, and then it will be retired. Therefore, in cost calculations, allowance must be made for this 20-yr life expectancy as the only means of estimating what total volume of energy should assume the burden of the cost of buying and installing the turbine.

---

[57] Prof. of Finance, Columbia Univ., New York, N. Y.

The writer is well aware of the hazardous nature of forecasts as to the future retirement dates of turbines and other assets used in the production and supply of electricity. The difficulties are so great that a plausible, although not convincing, case can be made for a refusal to make the forecasts for purposes of standard, "financial" accounting. In "cost" accounting, however (which is the only type of accounting that concerns the subject of this Symposium), there is no escape from the necessity of forecasting the future; and an assertion that life expectancy cannot be estimated is tantamount to an assertion that the cost of energy generation is indeterminate.

To restate the problem: In cost analysis, the problem of allowing for depreciation is the problem of cost pro-ration. It is the problem of tying up a given capital outlay—say $1 000 000 for a steam turbine built in 1937—with that estimated volume of energy which can economically be produced by the use of the asset for which the outlay was made. Strictly, depreciation is not a cost, because the entire cost of the turbine was in fact incurred in 1937, when it was paid for by the purchasing company, and no accounting mechanism by which this cost is gradually amortized over a period of years can alter the historical fact that the full cost was actually incurred in that year. Depreciation is a factor, however, that should determine what units of output should be held responsible for the total outlay and hence is a necessary factor in the calculation of average unit costs.

The foregoing statements are very general and, perhaps, very obvious; but the following is not so obvious and seems worthy of more attention than it has received. It concerns the allowance for depreciation due to prospective obsolescence in estimates of energy cost designed to show which of any alternative methods of producing energy is the most economical. Current practice in this respect is sometimes in error. Suppose that a manufacturer making large-scale use of electrical energy is in doubt as to whether to build a private steam plant or a private hydro-plant, since the alternative cost estimates come quite close together. The hydro-plant, say, would be scrapped in fifty years, because of silting and other elements of physical depreciation, but would not become obsolete before that date. The steam plant, with adequate replacement of wearing parts, would also have a 50-yr physical life but would become obsolete in twenty years.

Now ordinary practice would require that the cost of the steam plant be written off in twenty years, whereas the cost of the hydro-plant would be written off only in fifty years; and this mere difference in life expectancy might seem to turn the scales in favor of the hydro-plant because of its gentler liability to depreciation. Water power might appear to cost 5 mills; steam power might be shown to cost 5.5 mills. Therefore, the data would seem to say: "Let the manufacturer build the hydro-plant rather than the steam plant."

Is there not something wrong with this picture? Why should the choice lie with the hydro-plant simply because water power has already come close to realizing its maximum efficiency whereas a much better steam plant may be available in the near future? To be sure, if the manufacturer can afford to postpone building any power plant, his expectation that a better steam plant will be available within a few years may possibly justify delay in building; but if he must build some plant now, why should he decide against the steam plant merely because the hydro-plant, once built, will take a longer time to become obsolete than the steam plant?

This is a problem that the writer has not yet solved to his own satisfaction; but he suggests that, in calculating alternative costs, the engineer should not burden his putative steam-plant costs with any allowance for obsoleteness antedating the retirement date of the hydro-plant, unless he also makes a specific allowance for the lower operating expenses that the manufacturer will be able to enjoy during the remaining life of the hydro-plant if he now builds a steam plant, retires it in twenty years, and then builds a more efficient new steam plant. In practice, however, an engineer can scarcely forecast the operating expenses of a steam plant to be designed twenty years in advance of the present time. His ignorance, therefore, may force him to assume that the annual expenses of steam generation, during the longer life of a hydro-plant, will remain what they are to-day; but if he makes this assumption, he should not burden his steam-plant cost with an allowance for a premature obsoleteness which, should it materialize, would put the owner in a position to take advantage of the very improvement that will have rendered his present steam plant obsolete.

To state the point in another way: In choosing between the construction of a high-cost hydro-plant with a probable useful life of fifty years, and the construction of a lower-cost steam plant with a probable useful life of twenty years, the choice cannot be based intelligently on a mere comparison between the average cost of the hydro energy for the longer period and the average cost of the steam energy for the shorter period. Instead, the comparison should be between the cost of the hydro energy over the 50-yr estimated life of the hydro-plant, and some average cost of energy for the same period produced, first by a present-day type of steam plant and then by whatever type of new plant will become economical when this steam plant is retired. However, if it is impossible, for practical reasons, to estimate what it will cost to produce energy by a new plant designed twenty years from the present date, and if, therefore, the cost analyst must assume the continuance of the present annual steam operating expenses for the entire 50-yr period, he should not contradict this assumption by calculating an annual allowance for steam-plant depreciation that assumes a state of obsoleteness within twenty years. If the steam plant should indeed become obsolete in twenty years, that very fact would mean that the company which built this plant could then reduce its energy costs by installing a new plant. No similar opportunity to take advantage of rapid improvements in technique will apply if the company decides to build the hydro-plant, because the costs of hydro generation are largely fixed costs that are unavoidably "sunk" as soon as the plant is constructed.

The writer is not at all sure that he is right in this tentative solution of the foregoing problem; but the problem is a real one and has not yet received adequate study by specialists in cost accounting. In general, the problem arises because obsolescence, unlike physical deterioration, is only the adverse side of a good situation—of an opportunity to reduce costs in the future. The question arises as to whether cost accounting should not take direct cognizance of this good side instead of giving its sole attention to the bad side. To the important questions which Mr. Scharff has suggested for study, the writer would add this further question as offering an almost virgin field for engineers interested in private and public cost accounting.

It is pertinent to raise a question as to the definition of that multi-significant word, "depreciation." For practical reasons, the writer is inclined to favor the recognition of a number of alternative definitions, each of which might be characterized by some distinguishing adjective or adjunct. Although the restriction of the word to just one meaning would have obvious advantages, the difficulty of finding words for other accepted meanings is formidable. Engineers would probably find it difficult, if not impossible, to induce accountants, appraisers, and Courts to limit the use of the term to one single sense.

Mr. Scharff's proposal to use the term as an expression for the combined effect of a number of specified "causes" or phenomena (wear and tear, obsolescence, etc.), raises the question: Effect on what? In ordinary appraisal and accounting usage, depreciation is treated as something measurable in terms of dollars. Consequently, it is usually taken to denote a decline in value due to certain causes. Must one not say, therefore, "combined effect on value"? And must one not, then recognize that, since "value" itself is a word of many meanings, "depreciation" is indeterminate without reference to the type of "value" to which it is applied?

Finally, there is a distinction between depreciation as an economic value concept and deterioration as a physical concept. Referring, for example, to wooden poles, Mr. Scharff suggests (see heading "Physical Deterioration") that "deterioration through fiber rot in such a case may reasonably be measured in terms of decline in compression and bending strength at standard fiber stresses." Yet, the decline in the value of the pole resulting from the process of rotting (depreciation) is by no means closely correlated with the decline in compression or bending strength. Similarly, an ornamental candle, half used up (or even burned half-way down to the top of its candlestick) is worth less than one-half its value new, because of the serious impairment in its ornamental qualities. The writer suspects that appraisal engineers, in their testimony in valuation cases, are sometimes guilty of making unwarranted transfers from engineering concepts such as that of "per cent condition" to economic concepts such as that of "per cent of value new." Precisely what is meant by "per cent condition"? The writer has never found an appraisal expert who could answer that question with even a decent approach to scientific precision.

R. ROBINSON ROWE,[58] M. AM. SOC. C. E. (by letter).—Under the heading, "Undeveloped Hydro-Electric Power," Professor Barrows has tabulated the "horse-power, potential water power (available 90% of time)" for the ten leading States. The writer has been greatly impressed by the quantity of cheap water power available in Southeastern Alaska (sometimes called the "Panhandle"). Although not proposing Statehood for all or any part of Alaska at this time, it is suggested that the southeastern part has an area comparable to that of many States, a population density not unlike that of Nevada, a climate less rigorous than that of many States, and social, political, and economic qualities equivalent to those of many States at the time of admission.

Comparison with power resources of leading States seems in order and the comparison is more striking if expressed in terms of power density. This density has been computed on the basis of political boundaries, but, if data were available, and density were computed to water-shed lines, the comparison would be still more impressive. Less than 5 000 hp of that surveyed is available from water that has crossed the political boundary of the area. The data in Table 17 have been compiled from Professor Barrows' table, a survey[59] of Southeastern Alaska made for the U. S. Forest Service by the writer, and data from publications of the U. S. Geological Survey.

TABLE 17.—WATER POWER DENSITY

Item No. (1)	State, or region (2)	Horse-power, potential water power* (3)	Area, in square miles (4)	Horse-power per square mile (5)
1	Washington	8 800 000	69 127	127
2	New York	4 300 000	49 204	87
3	Connecticut	330 000	4 845	66
4	Oregon	4 400 000	96 699	45
5	Arizona	3 700 000	113 956	33
6	Idaho	2 700 000	83 888	32
7	Tennessee	1 300 000	42 022	31
8	California	4 600 000	158 997	29
9	Southeastern Alaska	790 000	35 527	22
10	New Hampshire	200 000	9 031	21

[58] Assoc. Bridge Engr., State Dept. of Public Works, Sacramento, Calif.

[59] Report to be published shortly by the U. S. Forest Service and the Federal Power Commission.

Summarized, the survey of Southeastern Alaska power yielded the following totals:

Hydro-Power Potential:		
Average yield, in horse-power		1 007 590
Primary yield, in horse-power		790 470
Hydro-Power Developed:		
Average yield, in horse-power	36 064	
Abandoned yield, in horse-power	−8 190	
Net, active yield, in horse-power		27 874
Installed:		
Turbines, horse-power		40 676
Generators, kilovolt-amperes		25 811

Many of these powers can be developed for less than $50 per hp, as the physiography is favorable to low cost and most power-house sites are at protected tidewater. Storage reservoirs can be developed from "hanging lakes," in elevated valleys left by receding glaciers close to tidewater. Heads average 400 to 500 ft, with a maximum of 2 400 ft. Conduit lengths generally approximate five times the head and mountain spurs will usually permit about 70% of the conduit to be a low-pressure or a moderate-pressure line. Precipitation is high, sea-level annual means ranging from 27 in. at Skagway to 180 in. at Little Port Walter, and annual means of precipitation and run-off show less departure from norms than for the Pacific Coast States.

V. B. Libbey,[60] Assoc. M. Am. Soc. C. E. (by letter).—The writer doubts whether a technician entering the forum constituted by the *Proceedings* of the Society to discuss "depreciation" as applied to units of public utility property is free to write his own definition of the word, and he believes it imperative that this point should be brought out in the discussion of Mr. Scharff's paper.

The larger phase, of course is whether or not the concept presented is necessary or usable in the philosophy or technique of rate determination or other problems in engineering economics. This discussion will be limited to a consideration of the first proposition, with the larger question entering only incidentally.

"Depreciation" (the word must remain in quotation marks until a definition is adduced) of units of a public utility property is a most important factor in the determination of rates (especially as the rates are determined by administrative boards) in that it appears as an element of "value" and again as an element of expense. As stated by the Special Committee on Valuation and quoted by Mr. Scharff:[21] "Perhaps there is no single subject * * * that has caused more trouble than depreciation." Continuing (in the following sentence not quoted by Mr. Scharff) the Committee stated: "This has been due to various causes perhaps not the least of which has been confusion in the use of the term."

---

[60] Supt., Hawaiian Contracting Co., Ltd., Honolulu, Hawaii.

The deliberate introduction of confusion into rate proceedings in the forum constituted by public utility commissions acting as judicial bodies and subject to review by the Courts seems to be an accepted—if not highly approved—technique followed, in the legal approach to rate-making by counsel employed as advocates of low rates or high rates. In such instances, the proceeding partakes of a trial, and the facts are to be determined on the weight of the polar evidence presented by advocates approaching the matter from the two extremes, and employed and paid in accordance with their ability to influence the decision.

On the contrary, in the engineer's forum the object must be to eliminate confusion. The engineer seeks to determine the operations to which the concept is subject and, if possible, fix the concept by fixing the operations. In this respect the engineer must maintain an attitude toward depreciation much the same as that which he maintains toward length, velocity, and other phenomena with which he deals.

Even in proceedings before commissions confusion as to the use of the term has been greatly reduced, and among economists, engineers, accountants, etc., the concept of the word has been crystallized to mean loss of value arising from causes that bring about ultimate retirement.

In a remarkable manner the Special Committee on Valuation, beginning its work in 1911 and reporting in 1916, viewed "depreciation" in exactly this manner. Only in 1909 had the United States Supreme Court, with a background of legal philosophy as to property and value and its body of laboriously built precedent, recognized "depreciation" as a loss of value. Even so the Court had left it as a metaphysical concept not clearly related to its causes. The Committee of engineers trained in an objective approach, went directly to the causes. Accustomed to the use of mathematics as a tool for the transposition of an unusable set of "knowns" to a usable "expression," the Committee set forth a method of arriving at "depreciation" which satisfied the requirements of fairness and convenience that were involved in the concept and were believed to conform to law. If "remarkable" carries a suggestion of surprise, then "noteworthy" is a better word, because the engineers acted only in accordance with the customary engineering method of approach.

The following is a definition of "depreciation" that may be obtained from the text of the report of this Special Committee by a grouping and re-arrangement of words and phrases, with only slight modification:

> "Depreciation," as applied to depreciable electric plant, means the loss in service value not restored by current maintenance, incurred in connection with the consumption or prospective retirement of electric plant in the course of service from causes which are known to be in current operation and against which the utility is not protected by insurance. Among the causes to be given consideration are wear and tear, decay, action of the elements, inadequacy, obsolescence, changes in the art, changes in demand and requirements of public authorities.

The foregoing does not embrace the entire concept of the Committee but, in so far as it goes, it is in strict accord with it. It is the definition of depreciation formulated by the Federal Power Commission[61] in its new classification of accounts mentioned under the heading, "Public Utilities," in Mr. Scharff's paper.

This is also (except that "utility" is substituted for "electric" as the adjective qualifying "plant") the definition appearing in the Uniform System of Accounts recommended for adoption by the National Association of Railroad and Utilities Commissioners[62] and it is already quite generally adopted by State regulatory commissions. It is almost identically the definition of depreciation adopted by the Interstate Commerce Commission after extensive hearings on the matter of Depreciation Charges of Telephone Companies and Steam Railroad Companies.[63] It is almost, word for word, the definition appearing in Uniform System of Accounts for Telephone Companies prescribed by the Federal Communications Commission.[64]

To the layman, at least, it is a very accurate definition of depreciation as viewed by the Bureau of Internal Revenue in enforcing the provisions of the Income Tax Law.[65]

It is thus seen to be the definition of "the various administrative bureaus and commissions, necessarily called * * * into existence by the increasing complexities of our modern business and political affairs."[66]

As was not the case in 1916, when the report of the Special Committee on Valuation was rendered, this definition is now clearly accepted by the Supreme Court. In the Lindheimer *v.* Illinois Bell Telephone Company Case, Chief Justice Hughes, speaking for the Court says:[67]

> "Broadly speaking, depreciation is the loss, not restored by current maintenance, which is due to all the factors causing the ultimate retirement of the property. These factors embrace wear and tear, decay, inadequacy and obsolescence."

The engineers, the administrative bodies, and the Courts have thus tied depreciation to the essential observable operation—ultimate retirement. This is the connecting link between the abstraction, loss of value, and its causes without which there would be a "missing link." It is the integrating medium.

The definition does not fix the operation by which depreciation is to be measured, but it leaves the way open. At this stage, with past practices as to amortization so diversified it is probably expedient, reasonable, just, and equitable that this should be so. The engineer and other technicians who have a working acquaintance with mathematics can set up a rate of return and anticipated lives in years that can be agreed upon or determined by the weight of the evidence, and can develop formulas for present worth of future returns (value) that will permit arriving at loss of value. This, in the mind of the writer, will be "true depreciation." The annual charge to expense for depreciation so computed will be less than that under the "straight line" method of computation for expanding enterprises, such as power industries, and will permit lower rates that, in turn, will promote additional consumption.

[66] Mr. Justice Sutherland, Jones *v.* S. E. C. 298 U. S. 1 (1936).

[67] Public Utility Repts. (New Ser.), 292 U. S. 151 (1934).

Meanwhile, there are utilities which have followed a "retirement method" of accruing depreciation upon which it would work a great injustice to allow a return upon a "value" so computed. There are other utilities which have followed the "straight line method" of accruing depreciation. To compute rates on the higher value that would obtain and to include in expense the higher depreciation allowances that accure in the later life of units would impose an unfair and unreasonable burden on consumers.

As Mr. Scharff observes (see "Introduction"):

> "It is a sound financial principle that the value of a capital investment is equal to the present worth of the amortization of the investment plus the return upon the unamortized portion of the investment. This principle can be complied with, however, by the consistent application of any method of amortization whatever, * * *."

Equitably and reasonably the method chosen for amortization may be conceived of as determining loss of value and thus depreciation. This is the case if "anticipated returns" is the measure of value, and a "lack of relation to depreciation" becomes impossible.

Under the definition of depreciation presented herein and holding to the "present worth" concept of value, the rate-base of a utility may be fixed, whatever the method of amortization used in the past, and substantial justice will be done to owners and consumers. Acceptance of the definition and the "present worth" concept of value results in a workable plan for the inclusion of depreciation in rate determination or other problems in engineering economics that involve depreciation.

EDWIN D. DREYFUS,[68] ESQ. (by letter).—An important contribution to the problem dealing with depreciation is presented by Mr. Scharff who offers a novel plan for regularly checking up on the extent to which depreciation has actually progressed.

From a theoretical aspect, it is a simple matter to assume certain life probabilities and then make mathematical calculations for renewal or retirement accruals, more commonly called "depreciation." On such premises, a perfect balance can be obtained on a paper basis, as between the annual accrual rate and the accumulated reserves. The result of such calculations has the appearance of precision, and possibly the application of well informed judgment also may be implied accordingly. Extensive treatises have been published attempting to prove that accruals may be determined rather definitely. However, close investigation will reveal clearly that the depreciation problem is not quite so simple. As things happen to work out in Nature, there are always particular conditions or characteristics that Man must cope with and satisfy according to the practical necessities of the situation. The following will demonstrate this contention. A new business venture does not develop its full earning power at its inception; nor is it able to maintain earnings at required levels up to the time of final abandonment. Furthermore, it is not to be presumed that any business may be continued in perpetuity no matter how essential or vital it may be at the moment. Through the ingenuity of Man, the possibility of a substitute being developed is always in the offing.

---

[68] Engr., Pittsburgh, Pa.

The fact must always be remembered that through governmental regulation, the return is limited on the one hand, and that there is, on the other hand, no corresponding guaranty of the investment or protection against losses. By dealing too closely with various features of the regulatory problem, regulators, actuarians, accountants, engineers, and others might readily produce an undesired effect, causing real injury and thereby discouraging progress.

The estimating of allowances for annual accruals for depreciation is generally approached on theee much discussed bases: Straight-Line Method; Sinking Fund Method; and Retirement Method. There are some variations, but it is not important for the practical objective to include them in this discussion. The first two are based upon assumed life tables and the third, the Retirement Method, involves a careful gauging of the requirements from time to time—such as business experience in the past, progress in the arts, changes in governmental activity, and other influences would dictate.

In order that a better idea of the true depreciation problem may be had, the life of a business enterprise (and particularly one of a highly technical character such as that under consideration) is divided (see Fig. 35) into four stages: (1) Pioneering Period; (2) Accelerating Expansion; (3) Possible Arrested Growth; and, (4) Possible Serious Decline.

It is generally known that it requires time to place a new type of operation on a paying basis. A certain pioneering or developmental period is required to establish the business. In the initial stage of operation, since the plant is new, renewals and replacements will not be necessary for some time. To set up accruals immediately when physical conditions did not require it, or when earnings did not permit, would be unwise and, possibly, financially embarrassing, it being presumed that the project was conceived on a sound and economical basis taking into account the forecast of the growth in business and improvements in economy.

The second stage represents the time when the demand for services has rapidly increased until the territory or market has been fairly well saturated. As advance takes place in this period, the business is able to pay a fair return and accumulate a fund for retirements. Conservative management is guided by these practical conditions and gauges its reserve situation accordingly. It may speed up or slow down the rate of accumulation to the extent that it is able to foresee future changes. The percentage of reserves in relation to the investment to be protected may be maintained at a certain level for a period of time; or it may be gradually or rapidly increased as the circumstances may warrant.

When the third stage is reached and the growth of the business is definitely arrested, extra caution must be exercised. Many technological businesses

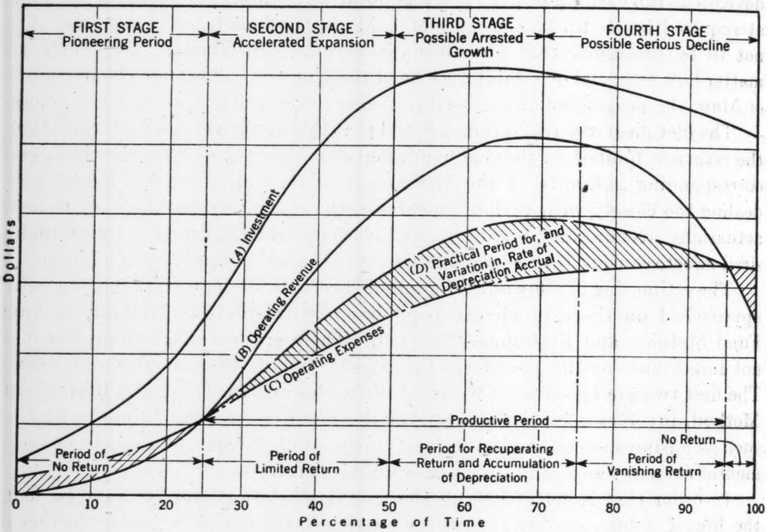

Fig. 35.—Possible Developments Requiring Consideration in Gaging the Accounts for Reserves for Ultimate Retirement

follow what is termed the biological or *S*-curve as typified by the investment curve, *A*, in Fig. 35. In this day of science and invention, a business is "placed on warning" when its volume does not keep pace with the growth of the population and the markets for goods and services. If a company delays too long in accumulating reserves, in proper degree and during the productive period, for the protection of the investment, it may readily happen that it will be overtaken by disaster. When the fourth stage is reached, any attempt to overcome shortcomings of the past would be futile.

The point that this illustration emphasizes is that as a result of various business situations the proper rate of depreciation accrual is often vastly different from that given by theoretical formulas based upon the assumed life of the items of property. The rate of accrual must vary necessarily with the productiveness of the business. It is for this reason that those responsible for management, frequently prefer to use a certain percentage of gross reserve to provide for maintenance and the annual accruals for renewals and retirements. If large sums are spent in any one year for maintenance and repairs, they have the effect of restoring the values in the property and, therefore, result in a lesser need for accruals.

Fig. 36 shows, relatively, the degree of protection provided for a given investment throughout the economic life of the enterprise under three methods of accruing for depreciation: Curve (1), Straight Line; Curve (2), Sinking Fund; and Curve (3), A Practical Method of Retirement. The first two methods do not deal with realities, and the inevitable consequences would be that they would fall far short of protecting the investment.

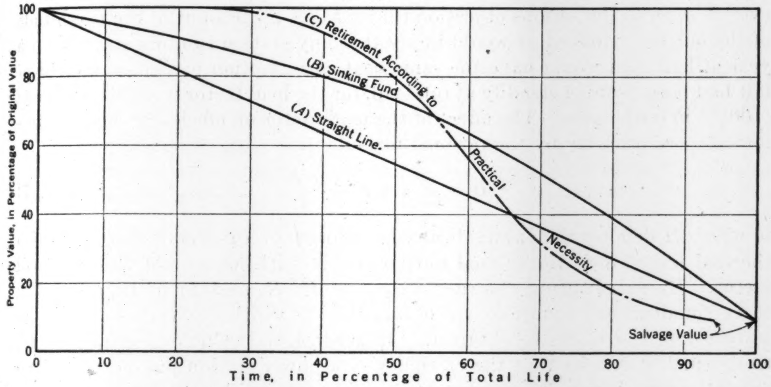

FIG. 36.—PROGRESS IN PROTECTING THE INVESTMENT IN PROPERTY BY DIFFERENT METHODS OF DEPRECIATION

The adoption of a theoretical treatment of depreciation for regulatory purposes without allowances for various practical features, may unwittingly and unlawfully deprive the owners of a substantial part of their property.

R. H. PARSONS,[69] ESQ. (by letter).—Since most of the operating charges of a given hydro-electric system, such as labor, management, maintenance, etc., are almost independent of the load, and as the capital charges are also constant, it is reasonable to assume, as Mr. Page does (see heading, "Effect of Load Factor"), that the cost of producing hydro power will be inversely proportional to the annual load factor. It must be remembered, however, that the consumer of electricity pays only for current at his own terminals, so that the capital charges and operating expenses of long transmission lines usually will have to be added to those of the hydro station before the minimum selling price of the power can be determined.

As far as fixed charges are concerned, of course, the same conditions apply to a steam power station, but the latter has the advantage that it can be built and extended as required by the demand at the time, thus reducing idle capital expenditure to the minimum; and the greater freedom in the choice of its location avoids the cost of long transmission lines. The fixed charges on a steam plant, therefore, are always substantially less than those of a hydro plant, so that as regards these charges only, the cost of steam-generated power to the consumer will be much less affected by a poor load factor on the system. In 1928, Professor A. G. Christie[70] suggested a formula of the type: British thermal unit per kilowatt-hour $= a + \frac{100\,000}{L}$, as showing the effect of the load factor on the heat consumption of a power station. This formula, however, is open to the serious objection that it takes no account of the magnitude of the output. Indeed, it would imply that any station running steadily for a year at half load would have the same heat consumption per kilowatt-hour as if it had been running steadily at full load, for the load factor would be the same (100%) in both cases. The effect of the load factor on efficiency can be determined more properly by the rational formula [71]:

---

[69] Engr., C. A. Parsons & Co., Ltd., Newcastle-on-Tyne, England.

$$H = a + b\,K + \frac{c\,K}{L} \qquad (7)$$

in which H denotes the annual heat consumption of a power station in British thermal units; K is the annual output in kilowatt-hours; and L is the load factor. By substituting recorded values of H, K, and L, in Equation (7), three simultaneous equations are obtained from which the values of the constants, a, b, and c, can be obtained. In general, the value of c is quite small, from which it follows that the efficiency of a power station producing a given annual output is not, in practice, appreciably affected by the load factor.

Referring to the remarks of Mr. Whitman the point that is often overlooked when comparing the capital costs of hydro and steam plants for a given duty, or when considering the part to be played by each in a combined system, is the advantage the steam turbine possesses in respect to overload capacity. By judicious design it is possible to construct a large steam turbine for a maximum output equal to practically double the most economical output, and to attain this result with only a very slight sacrifice of efficiency at the higher loads. In power stations, the use of turbines with large overload capacities was fully dealt with in a paper[72] read by Sir C. A. Parsons and R. Dowson at the World Power Conference, at Berlin, Germany, in 1930. It can be shown that turbo-generators having a continuous rating of 75% instead of the more usual 25% in excess of the most economical rating would provide a very large emergency capacity for about one-third the cost of installing extra plant for such emergency, thus giving a lower total cost per unit generated, which after all is more important to the consumer than spectacular thermal efficiency results.

In his recapitulation of the various features of the papers, Mr. Uhl, referring to the depreciation and obsolescence of steam and hydro plants, states that the average rate of depreciation may be as high as 5% for a steam plant and as low as 2% for a hydro plant (see "Elements of Power Cost: (2) Depreciation and Obsolescence"). Taking his own estimates of life, however, it is equally true that the depreciation of a hydro plant may be as high as 2.5%, and that of a steam plant as low as 3 per cent. There are turbo-generators running to-day in British steam stations which were installed 34 yr ago (in 1904), and it is found economical to keep them in service in spite of their obsolete steam conditions and design. Mr. Uhl (see heading "Steam and Water Power Combined") claims advantages for hydro plants over steam plants in the matter of starting-up time. It is certainly true that to start up a steam station with everything cold, would normally take several hours, but such a requirement is so rare that it need scarcely be considered. A turbine, equipped with slow-speed turning gear, can be put on the line from the cold condition in a matter of minutes should this be necessary, and boilers are now being developed which will provide steam from a cold start almost as quickly.

---

[70] "Peak Load Problems in Steam Power Stations," by A. G. Christie, read before the meeting of A.S.M.E. at its meeting in New York, N. Y., December, 1928 (F.S.P. 51-24).

[71] *The Engineer* (London, England), August 13, 1937.

[72] "The Use in Power Stations of Steam Turbines Having with Their Auxiliaries Large Overload Capacities," by the Hon. Sir Charles A. Parsons and R. Dowson, read at the Second World Power Conference, Berlin, Germany, 1930.

F. KNAPP,[73] ESQ. (by letter).—Power is stated by Mr. Uhl to be one of the few commodities the cost of which has steadily decreased whereas the cost of other commodities has been doubled or trebled. This statement requires some explanation. Public utilities combine two characteristics. They serve to supply the population with essential needs, such as those provided for by power stations, gas-works and water-works, railways, tramways, mail, and similar undertakings. The other and essential characteristic is the impossibility, both of a technical and economic nature, of allowing free competition because of the tremendous importance of the necessary capital outlay and the requirements of the right of way. The monopolistic nature of the public utilities is practically unavoidable and explains the acrimonious discussions among those favoring either the private monopoly controlled by the Government, or the public monopoly. At any rate, any form of monopoly can be tolerated only as long as it serves the public interest. Experience in the United States, where the system of the privately owned utilities predominates, has shown the weak spots and the difficulties of an effective control, leading to rather unhealthy conditions. In the case of the public utilities owned by the Government, the management comes, daily and hourly, in close and sensitive contact with the public, thus submitting the undertaking to an extremely efficient control. The prestige and authority of this type of public utility often represent a political weapon of outstanding importance.

The danger of a monopoly arises from the removal of the natural law of supply and demand, thus offsetting completely the regulation of the cost of the goods as established by competition. Making the assumption that the monopolist wishes to obtain a profit as great as possible (an assumption which is not far from the truth), the question arises as to just what level of cost will be necessary for him to reach his purpose. Choosing a high cost, the profit per unit sold rises, but the market probably becomes smaller. On the other hand, a large market permits him to reduce the cost per unit. Forced with this alternative, the monopolist certainly chooses the level that will make the product of cost per unit times the quantity sold, a maximum. This product being different for different cases, the monopolist will try to find this cost level by cut-and-try methods. Of deciding influence is the "elasticity" of the demand. It is now a well-established fact that the demand for power is extremely elastic; that is, a reduction of the cost to the ultimate consumer is accompanied by a considerable increase of the demand to such an extent as to make up for the loss caused by the original reduction. The significance of the elasticity of the demand for the fixing of the cost level makes it evident that the managements of every monopoly, and especially those of the electrical utilities, base their politics of cost upon a close (in most cases, statistical) knowledge of the coefficient of the elasticity of demand. Thus, in recent years, the cost of power is being reduced by economic reasoning, and has absolutely nothing to do with a philanthropic point of view.

---

[73] With São Paulo Tramway, Light & Power Co., Ltd., São Paulo, Brazil.

As stated by Mr. Page, there is nothing bad in either public or private ownership of electrical utilities, provided the public interest is being served. There are too many examples to prove that this has not always been the case. Nothing is gained by arguing about a few mills per kilowatt-hour in the cost of the current as finally supplied to the customer. What is necessary is a broad consideration of the social and economic objectives of the electrical utilities and the need of placing the public interest above any other consideration.

JOHN C. PAGE,[74] M. AM. SOC. C. E. (by letter).—The Second Symposium on Power Costs should prove most helpful in clearing away much of the haze that has surrounded some of the questions involved. The problem of computing the "obsolescence" factor, for example, has received particular attention, which has been clarifying. Only a few points raised in discussion require comment.

There seems to be general agreement, among those who participated, on certain fundamentals. These are: (1) That it is impossible to determine, on a general basis, whether steam or water power is cheaper, since each development must be considered separately, taking into consideration physical, economic, and technical facts which vary from place to place and from time to time, the sum total of which may favor either steam or water power in a given instance; and (2) that the electrical industry is monopolistic by nature, and whether privately or publicly operated, must serve in the public interest in self-justification.

Mr. Mason asks who has brought about the advancement in the type and knowledge of equipment for hydrogeneration in the past fifteen years, and answers that it certainly included no one but the private company, the manufacturer, and the private laboratory, thereby excluding all public agencies from any credit for this valuable public service. The record will show that many valuable contributions of such equipment for hydro plants have been made by designers in public employ. Certainly the designing section, Bureau of Reclamation, through its laboratory work and otherwise, has improved high-pressure reservoir outlets (to name only one example); and others could be mentioned. Other public agencies also have made important contributions. In the advance of the industry by scientific means, there seems to be sufficient credit for all. In the general advance, there has certainly been no lack of co-operation between engineers and designers (no matter where or by whom employed), and the manufacturers.

Professor Mead states that interest during construction is seldom considered in computing the cost of Federal projects. This statement is true, unless too much emphasis is given to the word "seldom." Interest during construction is not computed on every Federal project. It was computed in the rates for Boulder Dam, to name one, and projects financed by loans from the Public Works Administration carried interest during construction, although the grant which usually accompanied the loan served to offset, in part, at least, the interest charges. The rates at which power is sold by all projects of the Bureau of Reclamation that remain under Federal control are computed to include interest on the capital cost chargeable to power.

---

[74] Commr., U. S. Bureau of Reclamation, Washington, D. C.

In this discussion, Professor Mead intimates that many of the Federal multiple-purpose projects, which include water power, are unwarranted. He indicates that information concerning their cost and their probable returns is not obtainable, and that the conclusion must be reached that they were not adequately planned. The writer calls attention to the contribution by Mr. McClellan, in discussing this Symposium, in which information as to the cost and repayment of the Boulder Dam and Grand Coulee Dam projects is presented. Data similar to these are available on other projects constructed by the Bureau of Reclamation. Although Mr. McClellan's discussion dealt primarily with cost and with returns, the planning and studies affecting these factors were not made more carefully than the investigations of other phases and features of the projects.

There may be instances, as Professor Mead hints, in which the desire to create work on useful projects outweighed other considerations as to desirability, necessity, or soundness, but the writer knows definitely of no such project. Those constructed by the Bureau of Reclamation (and the writer is qualified to speak authoritatively only for the Bureau) may have been begun quickly at the outset of the work programs; but that is no indication that thorough investigation had not preceded them. They were all carefully planned in advance, and some of them had been awaiting construction for long periods. Whether the conclusions upon which the plans were adopted were erroneous, only some historian in the future can say. The preparatory studies, however, were the best that could be made by able and qualified engineers at the time. The writer does not believe that any of these irrigation-power projects will be proved later to be unwarranted expenditures.

C. F. HIRSHFELD,[75] ESQ., AND R. M. VAN DUZER, JR.,[76] ESQ. (by letter).—Both Messrs. Christie and Elliott have reiterated a fact which the writers have emphasized—that judgment must be used in arriving at power costs from the data presented in this paper and others comprising the Symposium. The concrete examples contained in Mr. Christie's discussion, showing how the initial plant cost can vary widely with different local conditions, serves further to illustrate that generalizations as to power costs cannot be made.

The writers made no direct mention of reserve equipment and its effect on power costs because of the complications that would have been introduced. The subject could very well serve as the topic for a complete paper. The fact that reserve equipment is necessary for proper maintenance of service is one of the important reasons why few fuel-burning plants show annual capacity factors much in excess of 60 to 70 per cent.

---

[75] Chf. of Research, The Detroit Edison Co., Detroit, Mich. Mr. Hirshfeld died April 19, 1939.

[76] Engr., The Detroit Edison Co., Detroit, Mich.

It is unfortunate that the various ratios or factors used to express the significant characteristics of load have never been clearly defined by a recognized engineering body. The writers have observed in several of the papers and discussions that the same terms are used by the several writers with totally different meanings implied. For instance, the terms load factor, capacity factor, and use factor are ratios expressing entirely different characteristics of load. This fact should be recognized when comparing power-cost data.

H. K. Barrows,[77] M. Am. Soc. C. E. (by letter).—Mr. Mason's reference to over-capacity of plants recalls an unusual example of this condition in the Cobble Mountain plant of the City of Springfield, Mass., which is one of the features of their Little River water-supply system. This plant develops power from water for municipal supply as well as surplus water now available. Power use is during the eight hours of the day, at such times as needed for peak use in the power system of the Turners Falls Power Company, the lessees of this plant. To adjust conditions of flow to the 24-hr municipal supply needs, there is an intervening balancing reservoir between the power plant and the municipal intake.

The drainage area available is 45.5 sq miles and a net head of 330 to 420 ft, with complete regulation by storage. The wheel capacity is 33 000 kw under the maximum head of 420 ft, which corresponds to 1 160 cu ft per sec and about 25 cu ft per sec per sq mile of wheel capacity. As far as the writer is informed this is the highest flow per square mile of wheel capacity of any plant in the world, corresponding as it does to what would be a flood flow of this river. The yearly output is about 20 000 000 kw-hr, which gives the low capacity factor of about 0.09.

This plant is an example of what might be called a "super-peak load" plant —used only when most needed to help carry seasonal peaks in the load system. It cost about $4 200 000 including dam and reservoir, or $140 per kw, on the basis of 30 000-kw capacity. The power-plant alone, including penstock, surge tank, power-house, and equipment, cost $1 100 000 or $37 per kw.

Mr. Parker calls attention to the effect of long conduits as tending to increase the cost of high-head plants. As he notes, this tends to make the waterway for such plants a large proportion of the investment. On the other hand, this excess cost is often compensated by a smaller cost of dam, as well as of power-house and equipment, as will be noted by reference to Table 7.

The capacity of waterway is fundamentally based upon loss of head under average operating conditions; that is, wheel capacity times capacity factor, keeping in mind that true average losses should be used and not the loss corresponding to average flow or use of water. A low capacity factor, with a long penstock, however, may mean a somewhat greater carrying capacity in order not to lessen, too greatly, the maximum plant output.

For wooden pipes or flumes a greater allowance for depreciation should undoubtedly be made. Of course, it was impracticable for the author to vary this factor in individual cases for lack of detailed information as to structures.

---

[77] Prof. of Hydr. Eng., Mass. Inst. Tech., and Cons. Engr., Boston, Mass.

Mr. McClellan has contributed an interesting diagram (Fig. 34) of costs and tentative financing for the Grand Coulee Project on the Columbia River.

Mr. Rowe has called attention to the water-power resources of Southeastern Alaska, where, evidently, conditions are favorable to development, as compared to the leading States in this respect.

The author appreciates the interest shown in his paper and hopes that it may be of some service in the field of water power.

Maurice R. Scharff,[78] M. Am. Soc. C. E. (by letter).—Professor Bonbright has raised some most interesting questions. The writer agrees with him that it is a common error, in making economic comparisons of comparable installations, to disregard the relative probability of the development of obsolescence in different types of equipment and its resultant effect of probable frequency of replacement. The specific problem which he submits, of the correct comparison of a hydro plant to be scrapped in 50 yr and a steam plant to become obsolete in 20 yr, is an intriguing one. The writer suggests as a theoretical solution that the comparison should be made on the basis of the sum of the present worths of the total costs of the alternate projects, including capital costs and operating costs, for a period of time equal to the least common multiple of the assumed periods of replacement, or 100 yr. The writer agrees fully with Professor Bonbright as to the impossibility of anticipating the developments in steam power generation at the end of periods of 20, 40, 60, and 80 yr, respectively. Such an impossibility, however, does not prevent the submission of a suggestion as to the theoretically correct basis of comparison.

Mr. Burnell and Mr. Dreyfus have called attention helpfully to some of the practical management, and financial, considerations that must inevitably affect the practical determination of depreciation policies. The writer believes, however, that it will be most helpful for the engineering profession to continue the discussion and clarification of the engineering and economic aspects of the problem, leaving these practical financial and management considerations for application to the final engineering conclusions.

Mr. Thomas has emphasized the practical advantages of the application of the sinking fund, or compound interest method of treating depreciation to a large hydro-electric project. The writer has not intended to express any substantial disagreement with this point of view.

Mr. Libbey apparently agrees fully with the writer in his suggestions as to the relationship between annual and accrued depreciation and the equality between the value of the capital investment and the present worth of its amortization, plus the return upon the unamortized part of the investment. He seems to the writer, however, to state the conclusion from this premise in reverse when he suggests that the method chosen for amortization may be conceived of as determining loss of value and thus depreciation. It would seem more correct to the writer to say that the loss of value or depreciation should determine the method chosen for amortization.

In conclusion, the writer is gratified by the interest that has been shown in the subject and expresses the hope that engineers may continue to study the engineering and economic aspects of this difficult problem.

Paper No. 2036

ECONOMICS OF SEWAGE TREATMENT

By George J. Schroepfer,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Charles Gilman Hyde, and Frederic Bass.

Synopsis

A general analysis of the economics of various basic processes of sewage treatment is presented in this paper which draws attention to a number of influencing and controlling factors that affect the comparison of the various processes as applied to a specific situation. Data are presented on construction and operation costs and on the reductions accomplished by the various processes indicative of the usual conditions and of the range to be expected.

Introductory Statement of the Problem

Sewage treatment processes or combinations of processes are available for accomplishing varying degrees of treatment, including relatively complete removal of pollution, to meet the requirements of practically any condition. The number of processes available presents the problem of determining for a particular situation the method and degree of treatment which most economically and practically satisfies the needs of that definite problem. From a purely economics viewpoint, and for a fixed set of conditions, there is only one solution to the problem. However, a number of factors other than cost, affect the decision in a number of instances. A variety of considerations well known to sanitary engineers, serves to determine the degree of treatment necessary in a particular problem. Furthermore, the method capable of accomplishing the degree of treatment determined upon, is dependent upon a still larger number of influencing practical considerations. These practical factors may be of controlling importance and may make necessary the elimination of certain methods from considerations; or they may be of lesser import and serve merely to affect the judgment of the engineer in the determination of the most desirable and economical form of treatment.

Without question the most important item affecting the economic analysis of the sewage treatment problem is the determination of the degree of treat-

---

Note.—Presented at the meeting of the Sanitary Engineering Division, New York, N. Y., January 21, 1937, and published in April, 1938, *Proceedings*.

[1] Chf. Engr. and Supt., Minneapolis-St. Paul San. Dist., St. Paul, Minn.

ment necessary. In view of the fact that this question is definitely one which must be answered for every particular problem, no detailed discussion will be made herein. The fact that the degree of treatment required may vary from practically nothing to almost complete removal of pollution, necessarily affects the selection of the process of treatment in view of the limitations of the various processes now in use. The further fact that the cost varies with the degree of treatment provided, makes this latter consideration fundamental. The analysis of the type of process which will most economically provide the necessary degree of treatment is generally, from the standpoint of cost to the community, of much less importance than the determination of whether any intermediate, or relatively complete, treatment is necessary.

The aim of this paper is to show, in a general manner, the economic relationship between the various methods of treatment as well as between the different processes involved within the particular method.

Economics Problems Involved

In the selection of the degree and method of treatment best adapted to a particular situation, a variety of economics problems present themselves. Before proceeding with detailed discussion of the problems, it is well to consider them in general terms.

Disposal by Dilution.—The most common and generally the most economical manner of disposing of sewage and waste matter is to discharge it into the available receiving bodies of water—ocean, lake, river, or creek—either without treatment or after varying degrees of pollution removal.

As a natural drainage channel, a watercourse receives the normal surface pollution of the area tributary to it, and by the processes of natural purification converts the organic matter into stable, non-putrefactive matter. The processes underlying this change are physical, chemical, bacteriological, and biological in character, and depend for their effectiveness upon the existence of a proper and sufficient quantity of the elements and organisms which accomplish the changes. When, however, because of the growth of communities along such watercourse and their consequent discharge of sewage and trade wastes into the river or stream, the organic load becomes too great, the oxygen supply in the river is reduced, with a consequent impairment in the activity of the desirable organisms. When the balance between the oxygen resources and the oxygen demand of the organic matter discharged into the stream becomes unfavorable, some form of treatment becomes necessary to supplement the natural processes. The time when treatment becomes necessary and the extent of treatment required are dependent on the unfavorableness of the balance and the use to which the river will be put.

When adequate dilution is available, proportionate to the sewage and wastes discharged into it, the disposal of the sewage by emptying into a near-by lake or watercourse offers an economical solution to the sewage disposal problem. The proportionate degree of pollution that the river can receive is dependent on the characteristics of the receiving body of water, and the use to which it is put. In any event, there is an upper limit to the capacity of the stream or lake to receive polluting material and when that condition is reached, treatment to some degree, to relieve the unsatisfactory condition, becomes necessary.

Preliminary Treatment.—Many problems present themselves in connection with the economics of preliminary treatment. An important consideration is the most economical period of sedimentation when considered in relation to the reduction in suspended solids and bio-chemical oxygen demand (B.O.D.). The comparison between fine screening and sedimentation is worthy of consideration.

Secondary Treatment.—The advantage and economy of one type of secondary treatment as compared with others capable of performing the required degree of treatment present a number of problems. Within the various types themselves a number of considerations are of importance, such as the effect of various rates of application on the cost of trickling filters, the economical period of aeration in the case of the activated sludge process, and the effect of the addition of varying quantities of chemical in the case of chemical treatment. In all cases consideration must be given to the varying reductions accomplished, and to the controlling effect, in special cases, of the limitations on maximum reductions capable of accomplishment by the various processes. The extent to which preliminary treatment is carried before the secondary process is begun, as well as the type of such treatment, is an important economics problem.

Sludge Disposal.—One of the most important factors in arriving at a decision as to the economics of various types of treatment is the method of sludge disposal. Of the various methods available in any project, a study of the economics and applicability of such methods must be made, having in mind the local influencing or controlling factors. What might be a satisfactory and economic method under the conditions of one situation, might be objectionable or extravagant in another, stressing the fact that in sludge disposal, perhaps more than in sewage treatment, every situation must be considered by itself. Generalizations are difficult, and likely to be misleading when applied to sludge disposal. It is for this reason that the writer has refrained from evaluating the various sludge disposal methods in a general manner; for example, it is apparent that the controversial subject of the economics of sludge digestion or no digestion, in connection with disposal by vacuum filtration and incineration, cannot be answered in general terms when it is realized that variations in a large number of influencing factors definitely affect the results of the investigation. As a further example, vacuum filtration and incineration would not be justified in a situation where climatic and soil conditions and favorable plant environmental factors make disposal of digested sludge on sand drying beds particularly advantageous and economical. The variety of methods of sludge disposal available to the engineer, with their consequent questions of fertilizer production, power production with gas engines, and utilization of heat in incineration, considered in relation to characteristics of sewage and sludge, very definitely make the solution of the sludge disposal problem a specific one, with known conditions, rather than one capable of generalized discussion. The estimates shown herein for the various types of treatment are based upon digestion and air drying on open sludge beds.

However, the substantiating costs from various plants include a number of different methods of sludge disposal, such as digestion and drying, vacuum filtration, incineration, fertilizer production, lagooning, etc. Although the writer has similarly analyzed the costs for various methods of sludge disposal, and realizes the importance of this factor in the determination of the economics of sewage treatment, it was felt to be impracticable to include the analysis in this paper because of length limitations.

Miscellaneous.—For reasons of brevity a number of accepted forms of treatment, such as pre-aeration in connection with trickling filters, chlorination, intermittent sand filters, and Imhoff tank treatment, are not discussed, or if mention is made of them, the statements are of a general nature.

METHOD OF COMPARISON

To compare the merits of the different processes, accomplishing as they do, varying reductions in the strength of the influent sewage, the total annual charges of treatment by the various processes have been reduced to a cost per 1% reduction in suspended solids and B.O.D. Although, in special cases, bacteriological and nitrogen analyses may be important, the suspended solids and B.O.D. determinations are believed to furnish the most reliable general index of the efficiency of varying treatment processes.

It is the fact that the economic relationship between the various processes is tied in with, and depends very closely on, the analytical results obtained, that explains the large quantity of material included herein which is not strictly economics. Costs, analytical results obtained, adaptability, and other influencing or controlling factors must be carried "hand in hand" in the determination of the most favorable and economical treatment for a particular situation.

From a cost standpoint the various processes have been compared on the basis of the total annual charges per million gallons of sewage treated per 1% reduction in either suspended solids or B.O.D. Aside from the varying reductions accomplished by the different processes already discussed, this unit or yardstick does not take into consideration the fact that the higher the degree of treatment the greater the cost, as will be shown subsequently herein. In other words, the cost of removing the last 10% of suspended solids or B.O.D. in a sewage is proportionately much greater than the first 10%, as is generally recognized. This fact must be realized by the reader in comparing the costs on the unit used herein or, otherwise, conclusions will be drawn from the data which are contrary to the facts.

A further variation which the writer's unit does not definitely show is the effect of size of plant on the costs per unit or reduction. For various reasons the costs per million gallons in the larger plants are generally lower than in the smaller ones, and this variation is greater in some types of treatment than in others. This variation must also be considered in studying the data herein.

With these exceptions the method of evaluating the various processes is believed to be proper and correct and when cognizance is taken of the effect of these factors, a true picture of the cost and place for the various processes can be attained.

General Statement on Cost Data

The construction cost estimates presented herein are based on a level which, in general, prevailed from 1923 to 1930. They are believed to be reasonably close to the *Engineering News-Record* cost index of 200. Although, consciously or subconsciously, the writer had the general conditions existent in Minneapolis and St. Paul, Minn., in mind in preparing the estimates, the cost data are believed to be of general applicability in so far as cost level is concerned, except for unusual conditions. Substantiating cost data from actual plants bear out this statement. The previous statement applies, as noted, to the general cost level, but it is not intended to cover the multitude of factors which by their favorable or unfavorable effects might make one form of treatment more economical in a particular situation than another.

The term, total annual charges, as used in the paper, includes both operating and maintenance costs and fixed charges on the investment. Fixed charges include interest and amortization on bonds issued which is the usual method of financing sewage works improvement. A value for fixed charges of 6% of the construction cost annually has been used, realizing, however, that the magnitude depends for a particular situation on the form of the bond issue, the bond period, and the interest rate, which is influenced by a number of economic factors. This percentage represents an approximately average rate and is approximately the rate commonly secured. The effect of higher and lower rates will be shown in a later comparison.

Bond amortization should more properly be considered as a depreciation item which takes into account the comparative lives of the various plants, rather than one of bond retirement which may cover long or short periods, depending on local requirements and public feeling at the time of issuance. Allowance has been made for this fact by considering a relatively long bond period, and providing in the estimates for operation and maintenance cost an item of "Maintenance, Supplies, Repairs, and Renewals" to cover all such costs as might be necessary to maintain the plant in a first-class operating condition.

Characteristics of Sewage Considered

Although an attempt is made to make the comparisons and conclusions of general applicability, the condition and situation in Minneapolis and St. Paul have been uppermost in the writer's mind. This fact is obviously both necessary and beneficial, since the effect of certain features, such as characteristics of the sewage, capacity of plant, unit costs, etc., would make an abstract generalization worthless, if not even delusive. The characteristics of the sewage considered have an important effect on the results of any economic study of sewage treatment.

Except where specifically stated to the contrary herein, sewage having the following characteristics will be assumed:

Suspended solids, in parts per million..............	185
Five-day B.O.D., in parts per million..............	200

The foregoing values are the approximate strengths of the sewage from Minneapolis and St. Paul as determined in the latter part of 1927 and the early part of

1928, and because of their use in a number of economic studies to which reference will be made herein, have been used in this study. Except for the fact that the suspended solids content is rather low, the foregoing characteristics represent a sewage of normal strength, as evidenced by the fact that the average of the annual results at forty-two representative plants in the United States was approximately 239 ppm on a suspended solids basis and 198 ppm on a 5-day, B.O.D. basis.

ESTIMATED UNIT CONSTRUCTION COSTS

The estimates of construction costs of the various treatment plants used in this analysis are intended to be reasonably close to, but in general slightly higher than, the actual costs, since in such a general investigation as this, where fully developed plans and specifications cannot be prepared, it is obviously difficult to make a detailed and complete list of quantities to which unit prices can be applied. Being mindful of this fact, contingency items were added to provide for inevitable omissions, so that the estimates will show costs which will probably be found to be slightly higher, rather than lower, than actual bid prices; 15% was added to the estimated construction costs for engineering, contingencies, and omissions.

Because of the impracticability of presenting detailed estimates of costs of all the structures and equipment which make up a complete treatment plant, the estimated costs used herein are presented as unit cost estimates (that is, per cubic foot of tank, per acre-foot of filter, etc). This manner of presentation lends itself to a comparison with substantiating costs at actual existing plants. The following unit costs have been used in the estimates, except in the case of smaller plants, where somewhat higher costs have been used:

1.—Settling Tanks.—Estimates are based on cost of 54 cents to 62 cents per cu ft of effective capacity, which includes cost of tanks, mechanisms, influent and effluent channels, and various appurtenances, the value depending upon whether it is used in connection with trickling filter or activated sludge plants, and whether preliminary or final settling tanks are under consideration. In substantiation of the foregoing costs, an average of eight plants, most of which were constructed from 1930 to 1934 was 51 cents per cu ft, the lowest unit cost being 35 cents and the most expensive, 66 cents.

2.—Trickling Filters.—Estimates are based on a cost of $14 000 per acre per ft of depth, exclusive of cost of covers. An average of five trickling filter plants constructed from 1923 to 1929 was $13 170 per acre per ft of depth, the lowest being $10 060 and the highest, $15 600.

3.—Aeration Tanks in Connection with an Activated Sludge Plant.—An estimated cost of 52 cents per cu ft of effective aeration tank capacity was selected, this cost including operating galleries, but excluding air compressors, return and excess sludge pumps, power plant, air filters, and appurtenances. In substantiation of this value the average of four plants constructed from 1927 to 1931 was 51 cents, the lowest being 45 cents and the highest, 57 cents.

4.—Power Plant, Air Compressors, Sludge Pumps, Air Filters and Appurtenances in Connection with Activated Sludge Plant.—The estimated cost of these items is $7 500 per million gallons capacity. The average of six plants constructed from 1927 to 1934 was $8 800, the lowest being $5 100 and the highest, $12 200.

5.—Sludge Digestion Tanks.—Estimates are based on 35 cents per cu ft of effective capacity, including tanks, sludge pumps, galleries, heating plant, mechanisms, covers, etc. An average of nine plants constructed from 1928 to 1933 was 32 cents, the lowest being 21 cents and the highest, 44 cents.

6.—Sludge Storage Tanks.—Estimates are based on a cost of 20 cents per cu ft of effective capacity, including covers. An average of six plants constructed from 1928 to 1933, some of which were uncovered, was 18 cents, the lowest being 12.5 cents and the highest, 27 cents.

7.—Sludge Drying Beds.—Cost estimates are based on 60 cents per sq ft of open beds, the hand-cleaned type, including transportation facilities. In substantiation, the average of twenty-two plants, constructed from 1925 to 1933, was 55 cents per sq ft, the lowest being 26 cents, and the highest, $1.03. Considering only the nine larger plants the costs averaged 48 cents per sq ft. Substantiating costs do not include hauling equipment.

SCREENS AND GRIT CHAMBERS

General.—Although not productive of as high removals, proportionately, as other units of the treatment plant, the removal of the larger material by screens and the heavier material by grit chambers is none the less important. The efficient and economical operation of the remainder of the plant makes the inclusion of these units a necessary adjunct to a well designed plant, especially if the sewage is from a combined system.

The early installations of screens and grit chambers were simple, involving usually manual removal of screenings and grit; but recently mechanical and automatic equipment has become available and its use in connection with later plants has resulted in more efficient operation of these units.

Bar Screens

Removal Accomplished by Bar Screens.—A study has been made of the operating results of 117 bar-screen installations, in which the average removals varied with the size of the opening, somewhat as follows:

Clear opening, in inches	Average quantity of screenings, in cubic feet per million gallons
2.00	0.9
1.50	1.2
1.00	3.1
0.75	5.3
0.50	8.6

Usually the maximum peaks are 200% of the average quantity, but in some cases they range as high as 500 per cent.

With raw sewage containing approximately 200 ppm of suspended solids, approximately 1.5% of the suspended solids may be removed with screens with 1-in. clear openings and about 3.5% with screens of 0.5-in. openings.

Method of Disposing of Screenings.—In forty-nine plants concerning which data were available, sixteen plants disposed of screenings by incineration, eleven by grinding, twenty-one by burial and one by digestion. The costs for incineration range from $1.07 to $9.30 per ton, and by burial from $0.50 to $5.00.

Grit Chambers

Removal Accomplished by Grit Chambers.—In view of the varying designs of grit chambers, as well as of the characteristics of the sewage entering them, it is to be expected that the percentage of suspended solids removed will vary accordingly. The average quantity of screenings removed in thirteen plants investigated was 3.7 cu ft, or 0.14 cu yd per million gallons, the minimum removal being 1.16 cu ft, and the maximum, 7.0 cu ft per million gallons. The foregoing data are based on yearly, or at least on monthly, averages. Daily maximums have been observed as high as 80 cu ft per million gallons.

Based on the average removed of 3.7 cu ft per million gallons, and a raw sewage containing 200 ppm of suspended solids, grit chambers may be expected to remove about 5.5% of the solids contained in the sewage reaching them.

Total Quantity of Solids Removed by Screens and Grit Chambers.—With screens with 1-in. clear openings and grit chambers of usual length and cross-section proportionate to flow, it is reasonable to expect a total removal of about 7 cu ft per million gallons, corresponding to a total reduction in suspended solids of about 7% for a sewage of normal strength. The removal of B.O.D. is proportionately much less.

Construction Cost of Screens and Grit Chambers.—A wide range in the cost of building screens and grit chambers is indicated, dependent on the simplicity or elaborateness of the installation, the costs varying in twelve installations investigated from approximately $150 to $1 200 per million gallon capacity. The data indicate a total average cost, including mechanisms, approximating in the smaller installations, a value of $1 000 per million gallon capacity, and ranging in the larger installations to $600 per million gallon. A still further variation exists in the data on operation costs of screen and grit chambers.

In explanation of the foregoing data it should be emphasized that the flow capacities are those of the grit chambers or of the intercepting sewers entering the plant, and are usually several times the capacity of the remainder of the plant. The costs of screen and grit chambers are included in those of the basic processes mentioned subsequently.

Fine Screens

Removals Accomplished by Fine Screening.—Data have been collected on the removals of suspended matter accomplished by fifteen fine screen installations, with clear openings from 0.20 in. and smaller. The data indicate an average removal of suspended solids of 5% with screens having clear openings of 0.2 in., 6.5% for screens with $\frac{1}{8}$-in. openings, increasing to 10% for screens with $\frac{1}{16}$-in. openings, and to 20% from screens with 0.02-in. openings. Most of the fine screen installations have screens with openings from $\frac{1}{8}$ in. to $\frac{1}{16}$ in. with the latter size predominating.

Construction and Operation Cost of Fine-Screenings Plants.—A study of seven installations indicates a construction cost range of from $5 000 per million gallon capacity in the smaller plants to $4 000 per million gallon capacity in the larger plants, and an operating and maintenance cost ranging from $2 per million gallon treated for smaller plants to $1 per million gallon in the larger plants. For installations with $\frac{1}{16}$-in. clear openings, the total annual cost per million gallons per 1% reduction in suspended solids is as given in Table 1.

TABLE 1.—TOTAL ANNUAL CHARGES OF FINE SCREENING PLANTS

Sewage treated, in million gallons daily	Total annual charges	Total annual cost per million gallons per 1% reduction in suspended solids
10	$10 000	$0.26
25	21 300	0.23
50	38 000	0.21
75	53 000	0.195
100	66 200	0.18

SEDIMENTATION

Reductions Accomplished by Sedimentation.—It is well known that the reduction accomplished by sedimentation is influenced by a large number of factors. A more complete discussion of the effects of the various factors was published[2] in 1933. These factors may be summarized as follows: (1) The characteristics of the liquid, under which can be included specific gravity and viscosity; (2) the characteristics of the solids, which include size, shape, specific gravity, concentration, coagulation, etc.; (3) the characteristics of the design, comprising detention period provided, velocity of flow, depth, and ratio of length to depth, inlets and outlets, baffling, etc.; and, (4) miscellaneous effects, such as currents caused by winds, eddies, and difference of temperature, biological activities, etc.

TABLE 2.—PERCENTAGE REMOVAL OF SUSPENDED SOLIDS AND FIVE-DAY BIO-CHEMICAL OXYGEN DEMAND SETTLING FOR VARIOUS PERIODS

Detention period, in hours	RAW SEWAGE STRENGTH, IN PARTS PER MILLION*								REMOVALS FOR SEWAGE OF AVERAGE STRENGTHS USED IN THIS ANALYSIS	
	50 to 100		100 to 200		200 to 300		300 to 400			
	S.S.	B.O.D.	S.S.	B.O.D.	S.S.	B.O.D.	S.S.	B.O.D.	S.S.	B.O.D.
0.5	26	12	34	16	40	18	42	20	35.5	12.5
1.0	36	19	45	24	51	27	53	30	45.5	21.0
1.5	43	24	50	30	56	33	60	36	51.0	26.5
2.0	47	27	54	34	60	37	63	39	55.0	31.0
2.5	50	30	57	36	62	40	65	41	57.5	34.0
3.0	52	32	59	38	64	42	66	43	59.5	37.0

* S.S. = suspended solids; and B.O.D. = five-day bio-chemical oxygen demand.

For a particular sewage one of the most important factors affecting the reduction accomplished by sedimentation is the detention period. In Table 2 the relationship between detention period and reduction in suspended solids and 5-day B.O.D. for sewages of various strengths is shown. The reduction increases sharply for a period of time, depending on characteristics of the sewage, and then gradually diminishes until a point is reached at which an increase in detention period does not result in an appreciable increase in solids reduction. From an economic standpoint, a balance exists between the cost of treatment and the reduction accomplished beyond which it is uneconomical to provide settling capacity. Furthermore, there is the possibility that under adverse conditions too long a period of settling may result in a degradation of the effluent because of septic action and the resulting gas buoyance of particles.

---

[2] *Sewage Works Journal*, Vol. V, No. 2, March, 1933.

The substantiating data used as a basis in preparing Table 2 consist of information available to the writer from more than thirty sedimentation plants scattered throughout the United States. A total of approximately 140 values was considered, each representing a monthly, up to a yearly, average. The settling periods shown are based upon theoretical, computed detention periods.

TABLE 3.—CONSTRUCTION, AND OPERATION AND MAINTENANCE, COSTS OF SEDIMENTATION PLANTS OF VARIOUS CAPACITIES

Plant capacity or sewage treated, in million gallons daily	CONSTRUCTION COST			OPERATION AND MAINTENANCE COST		
	Usual lower cost	Estimated in this analysis	Usual higher cost	Usual lower cost	Estimated in this analysis	Usual higher cost
10.....	$240 000	$325 000	$400 000	$17 000	$23 000	$29 000
25.....	550 000	725 000	900 000	38 000	50 000	62 000
50.....	980 000	1 300 000	1 600 000	68 000	90 000	110 000
75.....	1 350 000	1 800 000	2 250 000	94 000	125 000	160 000
100.....	1 720 000	2 300 000	2 900 000	120 000	155 000	200 000

Construction and Operating Costs of Sedimentation Plants.—In Table 3 estimates of construction costs and operation and maintenance costs are shown for plants of various capacities. These costs denoted as "estimated in this analysis" are based on a sedimentation period of 2.5 hr. Included also are usual lower and higher cost values which are approximately 25% below or above the estimated cost shown. Of twelve plants on which substantiating construction costs are available, the costs at one plant were less than the usual lower limit. Substantiating operation and maintenance cost data are available from ten plants of which four were less than the usual lower limit.

Economical Period of Sedimentation.—Because both the removals accomplished and the cost of sedimentation plants vary with the detention periods provided (but not in the same proportion) it is apparent that for a particular problem an economical period of sedimentation exists. A summary of data relative to this determination is shown in Table 4, in which the fourth and fifth columns contain the annual cost per million gallons per 1% reduction in B.O.D. and suspended solids, respectively. On a B.O.D. basis the economical period of settling is approximately 3 to 3.5 hr whereas, on a suspended solids basis, the economical period is approximately 1.25 to 1.50 hr. The foregoing statements apply to sedimentation in plants in which this is the sole process of treatment, and not to cases in which it is used in conjunction with secondary processes. Furthermore, it should be stated that for sewages with different settling characteristics as affected by detention period, or where costs are materially different, the aforementioned indications must be modified; and there may be situations in which higher reductions than are indicated to be economical are necessary or desirable, or other cases where the minimum of treatment is indicated, in which cases the economic study, of course, has no application.

TABLE 4.—CONSTRUCTION COSTS AND TOTAL ANNUAL CHARGES; SEDIMENTATION PLANT OF 100 MILLION GALLONS DAILY; AVERAGE FLOW WITH VARIOUS DETENTION PERIODS

Detention period, in hours	Estimated construction cost	Estimated total annual charges*	ANNUAL CHARGE PER MILLION GALLONS PER 1% REDUCTION IN:	
			5-day B.O.D.†	Suspended solids
0.5	$990 000	$173 500	$0.380	$0.134
1.0	1 325 000	203 500	0.265	0.123
1.5	1 595 000	228 000	0.236	0.122
2.0	1 845 000	250 000	0.220	0.124
2.5	2 070 000	269 000	0.216	0.128
3.0	2 290 000	288 000	0.213	0.132
3.5	2 500 000	304 500	0.213	0.137
4.0	2 700 000	321 000	0.217	0.143

* Includes fixed charges @ 6 per cent.
† Bio-chemical oxygen demand.

As a general statement, however, it can be said safely that where the pressing need is simply removal of solids, a short period (1 to 1.5 hr, or less) is indicated as being economical, and in cases where higher B.O.D. removal is desired detention periods of 2.5 to 3.5 hr may be economical. It should be mentioned in the latter connection, however, that such higher reductions in B.O.D. can usually be secured more economically through a variety of secondary processes.

TRICKLING FILTERS

Reductions Accomplished by Trickling Filters.—As in other processes the reduction accomplished by trickling filters varies in the different plants, depending on the characteristics of the sewage and design features. Data have been collected on the over-all reduction accomplished by eighteen trickling filter plants, based generally on annual averages. The weighted reduction, discarding data on plants in which the sewage was of unusual characteristics or concerning which a duplication of data existed on the same plant, is 85% on a B.O.D. basis and 84% on a suspended solids basis. On a B.O.D. basis, the maximum reduction accomplished in any plant was 94.5% and the minimum, 80%; whereas on a suspended solids basis the maximum reduction accomplished was 92.3% and the minimum, 70.5 per cent.

It is interesting to consider also the efficiency of the filter itself. In 1931[3] data indicative of the reductions from the point of application on the filter (effluent of preliminary sedimentation) to the point of leaving the final tanks (if included), were presented in some detail by the late J. A. Childs, M. Am.

---

[3] For a more complete discussion of this matter the reader is referred to *Civil Engineering*, Vol. 1, No. 15, December, 1931, p. 1391 (see especially Figs. 1 to 4).

Soc. C. E., and the writer. This information was collected in an attempt to determine economical filter loadings and rates of application. Reference to the source will reveal the following general observations: (1) Within limits, the percentage reduction in 5-day B.O.D. accomplished by trickling filters is independent of the strength of the sewage applied to the filters; (2) also within limits, the efficiency is independent of the rate of application; and (3) the efficiency is not, within a reasonable range, influenced by increases in combined volume and strength (loading).

These statements must be tempered in their conclusiveness in that they apply only within the limits for which data were collected, which, however, covered a rather wide range in both volume and strength. It is obvious that there must be an upper limit to the values for which they apply, but on a B.O.D. basis, that limit had apparently not been reached at any of the plants investigated, as no reduction in efficiency was in evidence.

These deductions make economic studies very difficult, since they do not indicate the most economical loading. If it were possible to load a filter continuously at some of the higher values indicated, low cost would result. Other factors, however, such as depth of bed, climatic conditions, characteristics of the sewage, size and character of the filtering media, method of application, dosing and rest periods, as well as many others, affect the magnitude of the economical loading in varying degrees. The data collected from the fifteen plants[4] considered in this study indicate an average reduction of the 5-day B.O.D., by secondary treatment with trickling filters of 75%, the lowest efficiency being 49% and the highest, 88 per cent.

It may be of interest to mention that since the collection of the foregoing data in 1929, trickling filter plants have been operated on a large-scale experimental basis with rates up to 20 and even 25 million gallons per acre per day. If it is demonstrated definitely that such high sustained rates of application are practicable in actual operation, trickling filters will be in a most advantageous position as far as the economics of treatment are concerned.

Construction, Operation, and Maintenance Costs of Trickling Filter Plants.—The estimated construction cost of trickling filter plants is shown in Table 5.

TABLE 5.—CONSTRUCTION, OPERATION, AND MAINTENANCE COSTS OF TRICKLING FILTER PLANTS OF VARIOUS CAPACITIES

Plant capacity or sewage treated, in million gallons daily	CONSTRUCTION COST			OPERATION AND MAINTENANCE COST		
	Usual lower limit	Estimated in this analysis	Usual higher limit	Usual lower cost	Estimated in this analysis	Usual higher cost
10.....	$900 000	$1 200 000	$1 500 000	$22 000	$30 000	$38 000
25.....	2 130 000	2 850 000	3 550 000	47 000	62 000	78 000
50.....	4 130 000	5 500 000	6 850 000	83 000	110 000	138 000
75.....	6 000 000	8 000 000	10 000 000	115 000	155 000	195 000
100.....	7 900 000	10 500 000	13 200 000	145 000	195 000	245 000

The tabulation of estimated costs is based upon a filter rate of 2.0 million gallons per acre per day on a filter 8 ft deep.

---

[4] *Civil Engineering*, Vol. 1, No. 15, December, 1931, p. 1391 (see especially Fig. 3).

Of twenty-six plants on which substantiating construction costs are available, the cost of one plant was higher than the usual higher cost and the costs at seven plants were lower than the usual lower limit.

As an indication of the effect of higher rates of application on the construction cost of trickling filters, it is estimated that with a rate of application of 3.0 million gallons per acre per day the construction cost of a complete trickling filter plant will be approximately 85% of the cost with a rate of 2 million gallons, whereas with a rate of 5.0 million gallons, the construction cost will be approximately 70% of the cost with a 2.0 million gallon rate. Some reduction in operation and maintenance cost would also be effected.

The estimated operation and maintenance cost of trickling filter plants substantiated by actual costs at other plants is shown in Table 5. Of twenty-two plants on which operation and maintenance costs are available, the costs at two plants were higher than the usual higher limit and those at two other plants were lower than the usual lower limit. As an indication of the distribution of the annual operating and maintenance costs the average of six trickling filter plants, varying from a capacity of 5 to 55 mgd, was as given in Table 6.

TABLE 6.—DISTRIBUTION OF ANNUAL OPERATING AND MAINTENANCE COSTS; AVERAGE OF SIX TRICKLING FILTER PLANTS

Item	Cost, in dollars per million gallons	Percentage of total cost
Labor and supervision	4.15	72
Maintenance, supplies, repairs, and renewals (includes power)	1.65	28
Total	5.80	100

Balance Between Various Processes.—Cost estimates have been prepared to determine the theoretical economical balance between the sedimentation and the secondary processes. It is evident that, unless the costs by both preliminary and secondary processes are identical, a variation in the detention period provided in the preliminary tanks will affect the over-all construction and operation and maintenance costs and the over-all reductions. Data relevant to this point, indicate that, at usual design rates, to increase the period of preliminary sedimentation from 1 hr to 2 hr results only in increasing the over-all reduction by about 2%, accomplished by raising the total annual charges by approximately 4% to 5 per cent. From a theoretical standpoint computations indicate that on a B.O.D. basis, the most economical period of sedimentation is the shortest one. However, there is a practical limit to the possibility of shortening the period of preliminary sedimentation as controlled by operation difficulties with filter nozzles and clogging of beds. It appears that a detention period in preliminary tanks of approximately 1.5 hr is a desirable and practical one for ordinary sewage. This has been demonstrated and is in accord with usual practice in design in this regard.

ACTIVATED SLUDGE PROCESS

Reductions Accomplished.—The activated sludge process is capable of accomplishing somewhat greater reductions, at least on a B.O.D. basis, than other processes. Data representing, in most cases, yearly or longer averages from nineteen activated sludge plants have been collected indicating an average reduction of 91.7% of 5-day B.O.D. and in suspended solids of 89.5 per cent. A weighted average (excluding certain plants in which the sewage was of unusual characteristics or, for other reasons, the data were not considered representative) indicates an average removal of B.O.D. of 92.5% and of suspended solids of 91.0 per cent.

The foregoing data refer to reductions accomplished by complete activated sludge treatment, including preliminary treatment. The reductions accomplished by the secondary process alone, including aeration and final sedimentation, for various periods of aeration of mixed liquor (sewage plus return sludge) for sewage of normal strength and characteristics are as follows:

Aeration period, in hours	Percentage reduction of 5-day bio-chemical oxygen demand
3	74.0
4	84.5
5	91.0
6	93.0
7	95.0

The foregoing reductions are substantiated by the average reductions in seventeen activated sludge plants. A total of thirty-five values covering operating periods usually of 1 yr, as well as of test plants, have been considered in the determination of the average values given. The list indicates that up to a period of approximately 5 hr, the reductions in B.O.D. increase markedly, after which an increase in the period of aeration does not result in appreciable increase in removals.

TABLE 7.—CONSTRUCTION, OPERATION, AND MAINTENANCE COSTS OF ACTIVATED SLUDGE PLANTS OF VARIOUS CAPACITIES

Plant capacity or sewage treated, in million gallons daily	Construction Cost				Operation and Maintenance Cost			
	Usual lower limit	Average for Aeration		Usual higher limit	Usual lower limit	Average for Air		Usual higher limits
		5 hours	6 hours			0.6 cubic foot per gallon	1.0 cubic feet per gallon	
10	$ 560 000	$ 700 000	$ 800 000	$ 940 000	$75 000	$ 90 000	$110 000	$125 000
25	1 280 000	1 600 000	1 800 000	2 120 000	150 000	185 000	220 000	255 000
50	2 500 000	3 200 000	3 500 000	4 200 000	250 000	310 000	370 000	430 000
75	3 700 000	4 750 000	5 200 000	6 200 000	340 000	420 000	495 000	570 000
100	5 000 000	6 300 000	6 900 000	8 200 000	430 000	520 000	615 000	710 000

Construction, and Operation and Maintenance, Costs of Activated Sludge Plants.—The estimated construction costs of activated sludge plants along with the estimated construction cost of activated sludge plants with detention periods of 5 and 6 hr are shown in Table 7, together with the usual lower and higher costs of this type of plant. An idea of the variation in construction costs is shown by the fact that of twenty-one plants on which construction costs are available, the costs at two plants were less than the usual lower limit and at one plant more than the usual higher limit shown.

Estimated operation and maintenance costs for activated sludge plants based on the use of 0.6 and 1.0 cu ft of air per gal are also shown. Of twenty-four plants on which operation and maintenance costs are available, the costs at five plants were less than the usual lower limit and at one plant, more than the usual higher limit shown. The operation and maintenance costs are based on a power rate of 1.0 cent for the larger plants, increasing for the smaller plants in accordance with usual schedules. In substantiation of the operation and maintenance costs shown in Table 7, and to furnish an indication of the composition of costs, the following costs at a number of representative activated sludge plants are shown: (1) Power costs: The average of fifteen plants in which power rates varied from 0.7 cent to 1.51 cents per kw-hr was $6.50 per million gallon treated; (2) labor and supervision: The average of fourteen plants was $6.35 per million gallon; and, (3) maintenance, supplies, repairs, and renewals: The average of fourteen plants was 1.74% of construction cost annually.

Economical Period of Aeration.—The fact that the reduction accomplished by activated sludge treatment is affected by the period of aeration, somewhat as shown previously, suggests the possibility of the existence of an economical period of aeration, at least from a theoretical standpoint. In Table 8 data of this nature are shown. The most economical period of aeration with normal sewage is calculated to be approximately 4.5 hr. The importance of determining the economical period of aeration from a cost standpoint, either in the design or in the operation stage, can be shown by the following: Considering secondary treatment alone (without preliminary treatment) an increase in the aeration period from 4.5 to 6 hr, increases the percentage reduction, 5%, the construction cost, 15%, and the total annual charges per unit of reduction, 5 per cent. At 4.5 hr, the total annual charges for secondary treatment are estimated to be $0.210 per million gallon per 1% reduction in 5-day B.O.D.

TABLE 8.—CONSTRUCTION COSTS AND TOTAL ANNUAL CHARGES—SECONDARY TREATMENT* BY ACTIVATED SLUDGE PROCESS—PLANT CAPACITY 100 MILLION GALLONS DAILY WITH VARIOUS DETENTION PERIODS

Period of aeration, in hours	Percentage reduction in 5-day bio-chemical oxygen demand of influent	Estimated construction cost	Fixed charges @ 6%	Annual maintenance and operation cost	Total annual charges	Total annual charges per million gallons per 1% reduction in 5-day bio-chemical oxygen demand
3.0.....	74.0	$3 445 000	$207 000	$402 000	$609 000	$0.226
4.0.....	84.5	3 845 000	231 000	425 000	656 000	0.213
4.5.....	88.0	4 005 000	240 000	436 000	676 000	0.210
5.0.....	91.0	4 235 000	254 000	447 000	701 000	0.212
6.0.....	93.0	4 640 000	278 000	471 000	749 000	0.221
7.0.....	95.0	5 040 000	303 000	494 000	797 000	0.230

* Preliminary treatment (that is, screen and grit chambers and preliminary settling) not included; disposal of sludge from secondary process included.

A shorter aeration period, approaching that mentioned previously, is substantiated by recent designs and operating data. It was only a few years ago that plants were designed and operated with detention periods in aeration tanks of from 6 hr and to 8 hr. More recently, periods of 5 hr and even shorter are more usual in design. It is important to realize that, in some cases, longer periods are necessary or desirable either because of unusual characteristics of the sewage, or because of the controlling features of the installation.

Balance Between Preliminary and Secondary Treatment.—Data relative to a determination of the balance between various processes are shown in Table 9, based on various periods of preliminary sedimentation, and an aeration period of 4.5 hr. The data indicate that from a theoretical standpoint the most economical reduction of B.O.D. is accomplished with the shortest period of sedimentation. From a practical standpoint, there is a limit to the extent to which preliminary sedimentation can be reduced as affected or controlled by difficulties in aeration tanks and sludge handling. Substantiation for the conclusion that secondary treatment is more economical than the preliminary processes, where a high degree of treatment is necessary, can be found in practice by the fact that relatively short periods of sedimentation or even fine screening has been provided in the larger plants. It appears that a practical and desirable range in period of preliminary treatment is from 0.5 hr to 1 hr. The method of disposing of sludge affects the economics to a certain extent.

TABLE 9.—TOTAL ANNUAL CHARGES OF ENTIRE ACTIVATED SLUDGE PLANTS WHEN PRECEDED BY VARIOUS PERIODS OF SEDIMENTATION PLANT CAPACITY, 100 MILLION GALLONS DAILY

(Based upon detention period of 4.5 hours with 20% return sludge in aeration tanks, and 1 cubic foot of air per gallon of sewage)

Period of sedimentation preceding aeration, in hours	Total over-all reduction in 5-day biochemical oxygen demand	Total annual charge per million gallons per 1% reduction in 5-day biochemical demand	Period of sedimentation preceding aeration, in hours	Total over-all reduction in 5-day biochemical oxygen demand	Total annual charge per million gallons per 1% reduction in 5-day biochemical demand	Period of sedimentation preceding aeration, in hours	Total over-all reduction in 5-day biochemical oxygen demand	Total annual charge per million gallons per 1% reduction in 5-day biochemical demand
0.25	89.5	$0.264	1.50	91.9	$0.281	3.00	93.2	$0.294
0.50	90.3	0.269	2.00	92.5	0.285	3.50	93.4	0.298
0.75	90.7	0.273	2.50	92.9	0.290	4.00	93.6	0.302
1.00	91.1	0.276	....	....	......	....	....	......

Air Requirements of Activated Sludge Process.—Data have been collected from fourteen plants on the quantity of air required in the activated sludge process. These data indicate that the quantity used for normal sewage varies from 0.4 cu ft to 2.5 cu ft per gal of sewage. The data show that of the total amount of air added, only 1% to 10% is actually used for oxidation of organic material in the sewage and even a portion of this may be derived from surface aeration. The remainder (from 90 to 99%) is used for agitation. The relation between influent strength in parts per million of 5-day B.O.D. and the cubic feet of air per pound of 5-day B.O.D. removed for the same data, is somewhat as follows:

Influent strength, in parts per million of five-day bio-chemical oxygen demand	Air required, in cubic feet of air per pound of five-day bio-chemical oxygen demand removed
100	1 700
200	900
300	650
400	500

In general, the quantity of air required per pound of 5-day B.O.D. removed, is greater for the weaker sewages than for the stronger ones. The possible economy of mechanical means of aeration, or a combination of air and mechanical methods is suggested from a study of the foregoing data for exceptionably weak sewages.

Period of Final Sedimentation.—The usual method of expressing the loading of final settling tanks following aeration is in terms of gallons of sewage per square foot of tank area per day. As an indication of the usual design practice, eleven activated sludge plants investigated, provide an average rate of approximately 900 gal of average sewage flow (not including return sludge) per sq ft per day, with the lowest design rate approximately 600 and the highest approximately 1 200. The average design rate at five of the larger plants was 830 gal per sq ft per day. Review of operating records indicates that rates from 800 to 1 000 gal per sq ft per day are practical and desirable rates for normal sewage. The rate selected should be based on a consideration of variations in flow (maximum and minimum with respect to average) and depth of tank. For example, with a 900-gal rate a 10-ft depth of tank provides a detention period of 2 hr; with a 12.5-ft depth, a period of 2.5 hr; and with a 15-ft depth of tank, 3 hr. In general, exceptionably shallow tanks should be designed with lower rates of application.

Chemical Treatment

Reductions Accomplished by Chemical Treatment.—One of the features of chemical treatment is its susceptibility to variation in reduction accomplished by varying the chemical addition. Data showing the reduction in suspended solids and B.O.D. from the results of experimental plants by various investigators and at six actual plants with different chemical additions have been collected. In these studies the chemicals added have been expressed in dollars per million gallons rather than parts per million because of the variety of chemicals used and their varying cost and effectiveness. Although a rather large range in reduction is indicated the data are believed to be sufficiently well substantiated and possible of attainment especially for well designed and well operated plants. Unusual sewages, of course, present an exception. The difference in effectiveness of chemical treatment at various plants should at least suggest the desirability of careful investigation before decision on the practicability of this type of treatment for a particular problem, as well as of the type of chemicals and various design features. The data collected (see Table 10) indicate the reductions in B.O.D. and suspended solids with various additions of chemicals for normal sewage and with reasonable detention periods in

TABLE 10.—REDUCTIONS ACCOMPLISHED BY CHEMICAL TREATMENT

Percentage removal of:	PERCENTAGE REDUCTION FOR THE FOLLOWING CHEMICALS ADDED, IN TERMS OF DOLLARS PER MILLION GALLONS			
	3.00	6.00	9.00	12.00
Bio-chemical oxygen demand..........	52	63	72	77
Suspended solids....................	69	77	84	88

the flocculating and settling tanks. Chemical costs used in comparing various plants are actual costs, except where data were not available, in which case actual chemical additions were used, applying the following chemical costs per ton:

Lime............................	$10
Chlorine........................	50
Copperas........................	17
Ferric chloride.................	50

Based on the additions of chemicals at the various plants, and on the foregoing costs, the average chemical cost per million gallons in the various plants investigated is $8.35; and the average reduction in B.O.D. was 67.3%; and in suspended solids, 83.8 per cent.

Construction, Operation, and Maintenance Costs of Chemical Treatment.— The estimated construction costs of chemical treatment plants are shown in Table 11. Of thirteen plants on which costs are available the costs at two plants are less than the usual lower limit and at two plants more than the usual higher limit. The construction costs of chemical treatment plants is likely to vary widely depending on the provisions of the design.

TABLE 11.—CONSTRUCTION, AND OPERATION AND MAINTENANCE, COSTS OF CHEMICAL TREATMENT PLANTS OF VARIOUS CAPACITIES

Plant capacity or sewage treated, in million gallons daily	CONSTRUCTION COST			OPERATION AND MAINTENANCE COST*		
	Usual lower cost	General average*	Usual higher cost	Usual lower cost	General average	Usual higher cost
10.....	$ 380 000	$ 500 000	$ 620 000	$26 000	$35 000	$44 000
25.....	750 000	1 000 000	1 250 000	52 000	69 000	86 000
50.....	1 300 000	1 750 000	2 200 000	84 000	112 000	140 000
75.....	1 800 000	2 375 000	3 000 000	115 000	153 000	190 000
100.....	2 200 000	2 950 000	3 700 000	143 000	190 000	240 000

* Exclusive of chemical added.

Data on operation and maintenance costs are shown in Table 11. Of six plants on which operation and maintenance costs are available the cost at one plant was more than the usual higher limit. In view of the varying cost of chemicals depending on the reduction desirable or necessary, the costs with various additions of chemicals have been added to the costs shown in Table 11 to prepare Table 12. Including chemicals the total estimated costs to accomplish various reductions are as shown in Table 12.

The costs shown in Table 12 are subject to the same variations with respect to usual lower and upper limits as shown in Table 11.

TABLE 12.—ESTIMATED COST OF REDUCTION BY CHEMICALS

REDUCTIONS ACCOMPLISHED		ANNUAL OPERATION AND MAINTENANCE COST				
Percentage of bio-chemical oxygen demand	Percentage of suspended solids	10 mgd	25 mgd	50 mgd	75 mgd	100 mgd
56	73	$48 000	$105 000	$185 000	$260 000	$330 000
69	83	65 000	140 000	255 000	360 000	475 000
79	89	80 000	180 000	330 000	465 000	625 000
82	91	85 000	190 000	60 000	515 000	680 000

EFFLUENT FILTERS

Removals Accomplished by Effluent Filters.—In the past several years, a number of installations of effluent filters consisting of beds of magnetite sand, usually of 3-in. thickness, cleaned by the action of a solenoid passing over the bed, have been made. Experimental data are also available on modified rapid sand filter beds, as used in water purification practice, and also on beds 12 in. deep, cleaned by jets of water; but to date (1938) no large-scale installations of these latter types have been made for which continuous long-time operating records are available.

Although filters of the previously described types may have a function as the principle method of treatment, their important application at present appears to be in conjunction with other basic processes, such as sedimentation, trickling filters, activated sludge, and chemical treatment, and only such use will be discussed herein. For this reason they are not considered in the comparison of basic treatment processes described subsequently. Data have been collected on the reductions accomplished by effluent filters (magnetite sand type) in certain plants. It will be observed from Table 13, which summarizes the data collected, that the reductions accomplished are a function of the strength of the filter influent, much the same as for trickling filters, except

TABLE 13.—REDUCTION ACCOMPLISHED BY EFFLUENT FILTERS FOLLOWING SEDIMENTATION AND CHEMICAL TREATMENT

Filter influent strength—bio-chemical oxygen demand and suspended solids, in parts per million	REDUCTION ACCOMPLISHED, IN PARTS PER MILLION			
	Following Sedimentation		Following Chemical Treatment	
	Bio-chemical oxygen demand	Suspended solids	Bio-chemical oxygen demand	Suspended solids
25.........	....	1	....	6
50.........	2	10	2	30
75.........	8	27	8	55
100.........	15	45	15	80
125.........	22	63	22	105

that the reduction is not a fixed percentage of the strength of the filter influent. The table is based on sewage of normal characteristics. As might be expected, the reductions in B.O.D. are somewhat lower than the reductions in suspended solids.

As in the case of trickling filters, the reduction accomplished does not appear for the same grain size to be affected by the rate of application, at least up to a limit of 4, or possible 5, gal per sq ft per min. A considerable variation occurs in practice in the filter rate varying in nine installations investigated from 1.8 to 3.0 gal per sq ft per min, the more usual rates being between 2.0 and 2.5. The rate to be chosen for design purposes should include a consideration of the reductions desirable or necessary, characteristics of filter influent, the sand size, variation in flow, and certain other factors.

Construction, Operation, and Maintenance Costs of Effluent Filters.—Data have been collected on the estimated construction costs of effluent filters, substantiated by costs of five installations and estimates from manufacturers. The cost of the equipment installed is estimated to be approximately 70% to 75% of the total installation cost. With upward flow filters constructed integrally with settling tanks, the extra cost of structures may be approximately 10% to 20% of the installed equipment cost. Based on rates of application of 2.5 to 3 gal per sq ft, the estimated construction cost per million gallons with separate structures vary approximately from $4 000 per million gallon of capacity for the larger installations to $5 000 per million gallon for the smaller installations.

Although data were available on some items of operation and maintenance costs, no actual substantiating data are available as to the total costs. They are believed, however, to be reasonably high for usual conditions. For various plant capacities the estimated operation and maintenance costs vary from approximately $1.00 per million gallon treated in the smaller installations to $0.70 per million gallon, in the larger installations.

Relative Costs as Compared with Other Processes.—This feature of cost comparison can best, and more accurately, be illustrated by application to a specific problem. A summary of data on an investigation of this subject prepared by the writer in connection with the Minneapolis-St. Paul project, is presented for this purpose. The design capacity of the plant is 134 mgd and the characteristics of the sewage are as assumed herein. The costs include only those chargeable to sewage treatment, and do not include the cost of sludge disposal, which was considered to be reasonably equal per ton of solids for sludge produced by other processes. On a suspended solids basis, the cost of filtration is approximately equal to chemical treatment if between 15 and 20 ppm are removed by filters, and to plain sedimentation if approximately 23 to 24 ppm are removed. On a B.O.D. basis, filtration is more economical than chemical treatment if between 12 and 15 ppm are removed, and as economical as sedimentation if approximately 16 to 17 ppm are removed. Based on the reductions by filters as shown in Table 13 and on the reductions expected by sedimentation and chemical treatment, it was estimated that the reductions accomplished by effluent filters for the Minneapolis-St. Paul project would be 18 ppm during chemical treatment and 31 ppm during plain sedimentation on a suspended solids basis; and 8 ppm during chemical treatment and 21 ppm during plain sedimentation on a B.O.D. basis. As will be explained subsequently, chemical treatment is required in Minneapolis and St. Paul only about 10% of the time, and, therefore, the removals during plain sedimentation are of more interest. The addition of filters in the Minneapolis-St. Paul project is expected to reduce the quantity of suspended solids in the plant effluent by approximately 6 000 tons annually.

Comparison of Various Processes

General.—From what has previously been mentioned it is apparent that a wide variation in construction, operation, and maintenance costs, and in reductions accomplished, obtains for the basic processes described herein. It is evident also that it is possible to obtain removals to meet the requirements of a particular situation, from nothing to relatively complete treatment by some of the basic processes or combinations with other processes. Having arrived at what seem to be reasonable basic cost and reduction data for normal conditions, this section of the paper is devoted to a comparison of the various processes, and a discussion of certain factors that affect their relative economy and thus serve to alter the general indications presented in the comparisons.

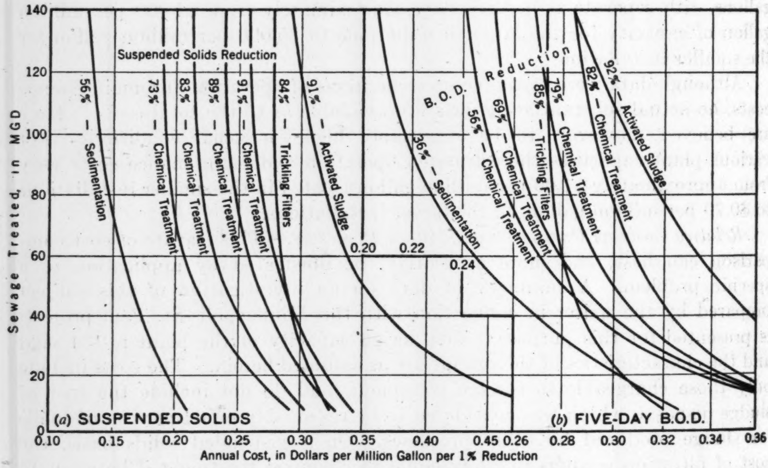

FIG. 1.—ANNUAL CHARGES OF VARIOUS METHODS OF TREATMENT

Comparison of Processes on Basis of Suspended Solids Reduction.—Using as a basis, the cost estimates and removals accomplished by the various processes, as already described, the estimated total annual costs per million gallons per 1% reduction in suspended solids, are shown for normal conditions, in Fig. 1(*a*). Selecting from this diagram three plant sizes for comparison, the costs may be summarized as shown in Table 14(*a*). It will be observed that on a suspended solids basis, the various processes, as applied to normal conditions, may be arranged in order of ascendancy of costs per unit of reduction, as follows: (1) Sedimentation; (2) chemical treatment to various degrees; (3) trickling filters; and (4) activated sludge. This arrangement does not hold for the smaller plants in which trickling filters may be more economical than some degrees of chemical treatment.

* For a removal of 79% B.O.D.

Comparison of Processes on Basis of Bio-Chemical Oxygen Demand Reductions.—Data relevant to this comparison are shown in Fig. 1(*b*) and for various selected plant sizes in Table 14(*b*). It will be observed that, on a B.O.D. basis, the relative economy of the various processes is less marked. For a plant of 100 mgd capacity, the order of economy for normal conditions is as follows: (1) Sedimentation; (2) chemical treatment to a B.O.D. removal of 77%; (3) trickling filters; (4) chemical treatment with B.O.D. removal greater than 77%; and (5) activated sludge treatment. However, for a plant of 20 mgd capacity the indicated order is: (1) Sedimentation; (2) trickling filters; (3) chemical treatment to various degrees; and (4) activated sludge.

The foregoing statements are irrespective of reductions accomplished. For processes accomplishing approximately the same degree of treatment the order of economy is altered. It should be emphasized also that the processes capable of the highest reduction, in general, cost more per unit of reduction.

Effect of Various Influencing Factors on the Comparison.—In view of the fact that the cost of the various processes accomplishing substantially the same removal are remarkably close, the necessity of investigating a number of influencing factors which affect the comparison in a particular situation, becomes apparent. It is important also to call attention to certain of these influencing factors which affect the comparison because, to this point, the analysis has of necessity been general, and the writer well realizes the impossibility of stating proper generalizations of many features of sewage treatment.

Effect of Degree of Treatment Capable of Accomplishment by the Various Processes.—The statement has already been made that the cost per unit of removal of the first 10% of pollution in a sewage or waste is less than the last 10%, indicating that processes capable of high removals, when compared on that basis will, in general, cost more per unit of removal than processes capable only of low removals. This fact can be shown very clearly by considering 35 (Fig. 1(*b*)) for a plant of 100 mgd capacity. For this condition, the costs can be summarized as in Column (9), Table 14(*b*). Thus, to effect the removals capable of accomplishment by activated sludge (that is, 92%) results in an increased cost per unit of removal of 35% over the cost by sedimentation. This fact must be borne in mind when considering the unit costs as presented herein.

It is because of the conditions stated herein that the degree of treatment necessary for a particular situation has such an important effect on the type of treatment selected and, therefore, upon the costs. The requirements of a situation may be such as to necessitate the adoption of a process or combination of processes capable of accomplishing high removals, in which case the cost of processes which result only in low removals is not pertinent.

Effect of Fixed Charges on Cost.—As already mentioned, this analysis has been based upon a uniform rate for fixed charges of 6 per cent. If, because of variation in interest rates or other considerations previously mentioned, these rates vary markedly, an important effect on the comparison of the various processes is observed. Table 15 illustrates the effect of this factor for a plant of 100 mgd capacity.

TABLE 15.—EFFECT OF FIXED CHARGES

Treatment	TOTAL ANNUAL CHARGES WITH FIXED CHARGES OF:		
	5%	6%†	7%
Sedimentation	$260 000	$285 000	$310 000
Trickling filters	750 000	857 000	964 000
Activated sludge	955 000	1 024 000	1 093 000
Chemical treatment*	775 000	804 000	833 000

* For removals of 79% B.O.D. and 89% suspended solids.
† From Table 16 and used generally in this analysis.

A low rate of fixed charges reflects favorably on the cost of processes more expensive in first cost and lower in operation and maintenance costs. Thus, for the conditions assumed, a reduction in fixed charges from 6% to 5% reduced the total annual charges of the trickling filter process by 12.5%, whereas the reduction in the activated sludge processes is 6.7%, and in the chemical treatment process only 3.6 per cent. The total annual charges per million gallon treated per 1% reduction in B.O.D. shown in Fig. 1(*b*), with various rates of fixed charges, are as given in Table 14(*c*), for a 100 mgd plant. It will be observed that whereas the cost per unit reduction of B.O.D. might be lower for the trickling filter process with fixed charges of 6%, with fixed charges of 7%, or more, the chemical treatment process becomes more economical. The effect of this factor in a particular installation must be considered in connection with studies of the economical form of treatment.

Effect of Sewage Characteristics.—The fact that the characteristics of the sewage may be such as to be more favorable to one type of treatment than to other types, must be considered in comparing processes for a specific situation. In fact, in some cases, the presence of inhibitive wastes makes some processes of the biological type impractical. Even in more normal sewages, strength and other characteristics affect both construction and operation costs of sewage treatment and sludge disposal. This influencing factor can be viewed more clearly by considering the individual processes—sedimentation, trickling filters, etc.

Sedimentation.—A number of considerations of sewage characteristics, such as its settleability, temperature, concentration, etc., are likely to affect the reductions capable of accomplishment and, therefore, for a given reduction, the period of detention necessary. It is well known, for example, that one plant with a detention period, of, say, 1.5 hr, may accomplish as great or a greater reduction than another plant providing a period of 2.5 hr. At least, part of this difference in behavior may be attributed to the sewage characteristics.

The processes following sedimentation, such as effluent filters, trickling filters, activated sludge, affect the detention period which should be provided, as already mentioned.

Considering equal reductions as being accomplished, a decrease in the detention period from 2.5 hr to 1.75 hr, reduces the construction costs of the entire plant by approximately 15 to 20 per cent. Assuming a decrease in construction cost of 15% and no reduction in operation and maintenance costs, such a decrease in detention period reduces the total annual charges of a plant of 100 mgd capacity by 8%, or the cost per unit of reduction in B.O.D. from 22 cents to 20 cents per million gallon.

Trickling Filters.—It is likely that, within limits, the rate of application of sewage on a trickling filter can be increased without affecting the reduction accomplished. Thus, it is conceivable that under both favorable design conditions and sewage characteristics it is possible to increase the average rate of application from 2 million gallon per acre per day as considered herein to as high as 5.0 million gallon in which case the construction costs will be reduced by approximately 30 per cent. Without considering possible reductions in operation and maintenance costs, the total annual charges will be reduced by approximately 22 per cent. In other words, the total annual charges per million gallons per 1% reduction in B.O.D. shown in Fig. 1(*b*), might be reduced from 27 cents to 21 cents. The effect of such a decrease in costs in the comparison of various processes is apparent.

Activated Sludge Process.—It may be possible under favorable conditions to reduce the detention period from 6 hr to 5 hr, and the quantity of air from 1.0 cu ft of air per gal to 0.6 cu ft. Under these conditions the construction costs might be reduced by as much as 9% and the total annual charges by as much as 12%, in which case the total annual charges per million gallons per 1% reduction in B.O.D., would be reduced from 30 cents to 26 cents.

Chemical Treatment.—In view of the varying effect of the addition of chemicals as affected by the characteristics of the sewage observed at various plants, it is apparent that, with a sewage particularly amenable to chemical treatment, the quantity of chemicals necessary to produce a given reduction may be materially less than for another less favorable sewage. If a reduction in chemical costs of $4 per million gallons can be effected for a sewage to which chemicals can be applied advantageously, a saving in annual operation and maintenance charges of approximately $150 000 annually for a plant of 100 mgd capacity will result, equivalent, in a condition where the chemical costs are reduced from $12 to $8 per million gallon for a 79% reduction in B.O.D., to a decrease in total annual charges approximating 19%, or to a decrease in the cost per million gallons per 1% reduction in B.O.D. from 28 cents to 23 cents.

Effect of Seasonal Variations in Degree of Treatment.—The preceding discussions are based on year-round treatment by the various processes. In certain situations, either because of variation in pollution, dilution capacity requirements, and possibly for other reasons, the necessity of a high degree of treatment is seasonal in character. Preliminary treatment may suffice for a part of the time, but for certain critical periods a higher degree of treatment is necessary. For such a condition, depending upon the percentage of time that such secondary treatment is necessary, it may be stated as a general principle that treatment processes with low initial costs and higher, proportionately, operation costs are the most economical. It is clearly evident, for example, that in a case in which a secondary treatment is indicated for 10% of the time

TABLE 16.—CONSTRUCTION COSTS AND TOTAL ANNUAL CHARGES OF VARIOUS TREATMENT PROCESSES: SECONDARY TREATMENT FOR VARIOUS PERIODS OF TIME; PLANT CAPACITY 100 MILLION GALLONS DAILY

3	Activated sludge	6 900	414	91	92	610	375	215	1 024	789	629
4	Chemical Treatment; Cost of Chemicals per Million Gallons:	2 900	174	..	..	....	....	....	....	....	....
4(*a*)	$4.00	....	....	73	56	335	235	170	509	409	324
4(*b*)	8.00	....	....	83	69	485	310	195	659	484	369
4(*c*)	12.00	....	....	89	79	630	385	220	804	559	394
4(*d*)	14.00	....	....	91	82	700	420	230	874	594	404

(as in Minneapolis and St. Paul), a process with high fixed charges on construction is definitely uneconomical as compared with a process with low first costs and proportionately higher operation costs for a short period of time. Data indicative of this variation for a plant of 100 mgd are shown in Table 16. With secondary treatment for twelve months, chemical treatment (at least with lower chemical additions) is the most economical, with trickling filters next and activated sludge most expensive. On a basis of two months' secondary treatment, however, chemical treatment is still more economical, activated sludge is next in cost, and trickling filters the most expensive. Here, again, the effect of fixed charges on construction on the economics is clearly demonstrated. Sedimentation during the entire year is included in the foregoing estimates, and no allowance is made for the maintenance of key men for the secondary treatment processes on the payroll, or for the periodic operation and checking of equipment as may be necessary in a number of cases. This has been done in a later estimate applicable to the Minneapolis-St. Paul situation.

The degree of treatment necessary during critical dilution conditions here, again, plays an important part in the determination of the type of treatment.

Effect of Commodities Cost.—As has already been mentioned construction costs vary under different conditions. In addition, operation and maintenance costs may vary depending upon cost of power, chemicals, labor, etc. In some cases, this variation may assume controlling importance in the selection. The effect of power production from sludge gas may be an important factor, especially in the selection of the type of sludge disposal. For reasons clear to the reader, especially the large variation possible in these factors and their relative effect on the various processes, the effect of commodity cost variation on the economics of treatment will not be discussed in detail, but has been mentioned in view of its important effect, in some cases, in the selection of the economical treatment process.

Effect of Hydraulic Head Available.—In certain instances, circumstances may be such as to make certain processes uneconomical when consideration is given to the hydraulic head available for operation of the treatment plant. As an example, the head necessary for operation of trickling filters may not be available in a specific problem in which case pumping of the sewage may be necessary. Even if sufficient head is available, its value in reducing the cost of intercepting sewers which would be possible in connection with other processes must be considered in the analysis. For example, in connection with the Minneapolis-St. Paul project it was determined that every foot of head saved in the plant was worth approximately $50 000 in reducing sewer sizes, when applied to the intercepting sewer system.

Effect of Design Features.—A rather wide range in the construction cost of a treatment plant can be expected as affected by a number of design features, such as provisions made for: Odor control, flexibility and dependability of operation, mechanical and automatic operation of equipment, etc. The personal opinions of the designer with respect to the conservativeness and the care with which the structural design is made, may affect the comparison between the processes. Furthermore, as knowledge has advanced (as it very markedly has during the 10 years, 1928–1938), economies have been affected in both design and operation. In the activated sludge process for example, the commonly accepted width of aeration tanks until 1930 was about 15 to 18 ft, whereas in recent years widths as great as 30 ft and more have been adopted, resulting in reduced structure costs and in air equipment and requirements. Similar economies have been, and will continue to be, made in other processes of sewage treatment.

Miscellaneous Factors Affecting the Comparison.—The writer has attempted to mention some factors of general application that affect the comparison of the economics of various treatment processes, but has by no means covered all such factors. The practical consideration that funds for operation are ordinarily difficult to procure may be considered sufficient justification in certain cases to affect a theoretical selection, and lead to the choosing of a process costing comparatively more to construct with attendant lower operation and maintenance costs. The method of sludge disposal selected or determined to be economical should be considered, together with the type of treatment, and, in certain cases, may exert an important influence on the selection. The size of the plant constructed as related to present requirements is a factor to be considered in the comparison. In special cases climatic and foundation conditions may have an influencing or even controlling effect on the selection. For various reasons all such factors cannot be covered in a paper of this nature and, therefore, the writer wishes to point out summarily that the generalizations made herein must be considered in the light at least of the major factors that affect economics of sewage treatment.

An idea of the effect of the various factors may be gained from a consideration of the substantiating data on construction and operation costs. Considering first construction cost: Of the 71 plants for which substantiating data are available 53, or 75%, are within a range of 20% above and below the estimated curves of costs shown in the curves. Of the 62 plants in which operation and maintenance costs are shown, 38, or 61%, are within the same range. Although this would indicate a fair substantiation of the estimates prepared for average conditions, it also serves to reveal the effect of a large number of factors that affect the costs in individual cases.

Economics of Various Processes as Applied to Minneapolis-St. Paul Project.—As a result of the relatively long period available for preliminary investigations in the "Twin City" project, both by the Metropolitan Drainage Commission over a period of five years, and the Minneapolis-St. Paul Sanitary District for two years, an unusual opportunity was presented for a careful determination of the relative economy of various processes and degrees of treatment. In various stages of the investigations, sedimentation, trickling filters, activated sludge, and chemical treatment were considered progressively. It was determined early that a high degree of secondary treatment was not necessary, and that preliminary treatment would suffice for all but a relatively small proportion of the time. The almost continuous record of river conditions over a 9-yr period was an invaluable aid in these determinations.

As a result of the investigations it was determined that preliminary treatment represented by sedimentation should be provided during the entire year, and that provision should be made to accomplish a reduction of as much as 70% of B.O.D. during certain critical periods estimated to be approximately 10% of the time. For periods of ten to fifteen years no secondary treatment whatever may be necessary, based on present river standards. The estimated costs as determined for the "Twin City" project are shown in Table 17. The estimates indicate the relative lower first cost of the chemical treatment process as compared with the activated sludge process. Based on year-round treatment the total annual charges of the activated sludge process (Treatment No. 3, Table 17) is $35 000 less expensive than the chemical treatment process (Treatment No. 1, Table 17). However, on a two-months basis (which is more than is estimated as necessary) chemical treatment will cost about $155 000 less annually than activated sludge treatment. Under different conditions the effect of the various influences previously mentioned may be such as to alter the determination.

TABLE 17.—ESTIMATED CONSTRUCTION COSTS AND TOTAL ANNUAL CHARGES OF VARIOUS TYPES OF TREATMENT PLANTS FOR MINNEAPOLIS-ST. PAUL, MINNESOTA

SUMMARY AND CONCLUSION

In an attempt to arrive at a solution of some of the economic problems involved in sewage treatment, the writer has presented data on the construction, operation, and maintenance costs, and reductions accomplished by some of the basic processes of sewage treatment, and has attempted to draw attention to certain factors which, in a particular situation, may alter such generalizations which of necessity have been made herein. Certain processes and combinations of processes have not been discussed because of space limitation and the writer wishes expressly to emphasize that this has not been done because such processes are not, in his opinion, of economic importance.

In conclusion, it should be stated: (1) That, although the writer has attacked the problem in a general manner, the effect of influencing factors in affecting conclusions relative to a definite project must be considered; (2) that in the writer's opinion the effect of such factors dictates that almost every project be analyzed separately; (3) that the fundamental and controlling economic factor is the degree of treatment necessary in a particular project; (4) that sufficient and well proved processes are available to satisfy, economically, the requirements of almost any problem that may arise; and (5) that the advances in the last five years, and the improvements that are certain to occur in the future, are of such magnitude as to require careful study in each project in order to reach an economical solution.

ACKNOWLEDGMENTS

Because it has been found impractical to acknowledge information and data furnished by others at its particular place of use, the writer wishes, collectively and summarily, to acknowledge his indebtedness for all such data used in this analysis. Data have been extracted from the engineering publications on the subject; they have been secured by direct visits to a number of treatment works; and by correspondence with the officials in charge, for all of which the writer expresses his gratefulness.

Special acknowledgment is due to the Metropolitan Drainage Commission and to Mr. Childs, its former Chief Engineer, whose assistance in connection with the preliminary studies, is noteworthy; and to the Board of Trustees of the Minneapolis-St. Paul District (Mr. C. C. Wilbur, Chief Engineer), for information relative to the "Twin City" project used in this paper.

DISCUSSION

Charles Gilman Hyde,[5] M. Am. Soc. C. E. (by letter).—Referring to the economics problem, in general, practically every engineering project demands consideration from three economic standpoints: Justification, selection, and proportioning.

In the usual case, private and quasi-public undertakings, such as manufacturing enterprises, office buildings, hotels, railway, water, gas, and electric systems, etc., must eventually justify themselves, in so far as their owners are concerned, on the basis of financial returns only. Enterprises undertaken by the public, such as water supply and highway systems, should also justify themselves from the economic standpoint, in considerable part, at least, if not wholly. However, many private, quasi-public, and public enterprises of the type in question yield intangible returns of distinct social and esthetic value that cannot be expressed in monetary terms. In those instances, where such dividends are relatively large, expenditures on the part of the public are justifiable either in the form of subsidies or of direct investment, as the situation may suggest. Rarely, however, does it appear that public monies are thus contributed to private undertakings even if the returns therefrom are of great social benefit.

The Economic Justification of Sewerage and Sewage Treatment.—It so happens that investments in sewerage and sewage treatment works can seldom be economically justified because their benefits are not to be reckoned in dollars. It is unquestionable that public health and comfort are immeasurably and directly improved by sewerage and to a less degree by sewage treatment. However, there seems to be no financial "yardstick" (for instance, in terms of the value of the human lives which might be saved by any particular system of works) by which the advantages of this indispensable public service can be measured. Occasionally, the treatment of sewage may lessen the cost of treatment of water taken from a source which would otherwise be more grossly polluted or possibly too polluted to permit of its use for water supply purposes. Occasionally, also, fish and shell-fish industries of commercial value may become possible where, except for such treatment, they would not. In such cases some form of estimate can be made of the economic value of sewage treatment.

It is believed, however, that in most cases and for the most part sewage treatment must be justified upon social and esthetic, rather than upon economic, grounds. Thereby odors are eliminated, unsightliness avoided, recreation in the forms of boating, bathing, fishing, and picnicking made possible, water sources rendered more available and amenable to successful treatment for industrial, domestic, and other public purposes, and, in general, a better and more satisfactory environment vouchsafed.

Problems which, perhaps, may be looked upon as coming within the category of economic justification sometimes present themselves in connection with the design of sewage treatment works. For instance, the question may arise: Can the dehydration of sludge and its preparation as a fertilizer be justified on the basis of the expected sales? Since the sludge must be disposed of in some fashion, however, this problem may also be regarded, and perhaps more properly, as one of economic selection—selection as between different methods of securing a final or end result.

Economic Selection in Sewage Treatment.—The paper deals only with problems of economic selection in sewage treatment planning and design. It is a noteworthy contribution of extreme value because of the truly enormous mass of worthy fundamental data that have been brought together and critically examined, because it is virtually a pioneer discussion of the major phases of this important matter, and because in no other single place, known to the writer, can the material or any substantial part of it be found. It appears that much of this information has never been published, at any rate in available form. Mr. Schroepfer deserves the gratitude of the profession for the faithful, untiring effort that he has put forth over a long period of time to bring these data together. He is to be congratulated upon their careful analysis and excellent presentation. His discussion of the many factors to be considered in this particular group of problems in economic selection is so comprehensive that little need be said further on that score.

Economic selection implies a choice, on the basis of involved costs, between different methods or machines for accomplishing a given, pre-determined result. In sewage treatment the desired character and condition of the effluent must determine the processes and mechanisms which are available and which can be utilized. The selection as between two or more possibilities will be made, wholly or in part, as the case may be, upon an economic basis. The most significant criteria of performance will ordinarily be the removal of suspended solids and bio-chemical oxygen demand, as suggested and used by the author. There will usually be other factors, not readily expressible in monetary units, which should be given due consideration, and these may be controlling in some instances. The author has wisely stated that such factors demand attention and that each local problem should be analyzed independently with respect to all influencing circumstances and conditions.

The total annual cost in every case should constitute the criterion of economic selection. This cost must comprehend all fixed and operating charges. The fixed charges must include interest, insurance, taxes (if any), depreciation, and maintenance. The operating charges must comprise all labor and overhead, and supplies of every kind not overlooking power, heating, and lighting costs.

Unfortunately, published data on sewage treatment costs too frequently present operating costs only, and omit the fixed charges. Both groups of charges should be presented, properly segregated. The total investment in the works covered by the operation cost data should be stated, together with the rate of interest thereon and the depreciation allowances. Maintenance expenses should be shown as a separate item. The author is to be complimented on the fact that he has taken both main categories of expense into due account.

It frequently happens that the investment costs of projects, selected to yield comparable effluents, are widely different. It is not always an easy matter to convince administrative authorities and the public that works requiring the larger initial investment may actually be the cheaper in the long run, all factors considered. It happens, also, that funds for the economically more advantageous scheme are often unavailable, or are assumed to be.

Different mechanical equipments may involve different types and shapes of structures which, in turn, may represent different investment and perhaps different annual costs. In such cases, if the performances are equivalent, the selection should be made upon the economic basis, unless local conditions dictate to the contrary.

It must be obvious that problems of economic selection present themselves not only with respect to entire projects, but also with respect to numerous features of these projects. For example, such problems arise in connection with the selection of screening, pumping, and aeration equipment, of types and shapes of settling basins and their mechanisms, and of sludge-handling and disposal procedures and equipments.

Economic Proportioning or Dimensioning in Sewage Treatment.—So much has been spoken or written upon the general subject of economic proportioning that designing engineers should be well aware of its importance and thoroughly acquainted with the calculation procedures. As in the domain of economic selection, however, there are many factors, aside from those of cost, which must be considered in determining the proper shapes, proportions, and dimensions of sewage treatment plant structures and equipments. The characteristics of sewage and sludge, of course, must always be borne in mind. Dependability is frequently of more importance than mechanical efficiency. Features and works that might appear to be most advantageous from an economic standpoint might actually perform so badly and demand so much operating attention that they might prove in reality (that is, in service) to be the more costly. The primary effort of the designer must be directed toward securing, with ease and assurance, the treatment effects that are sought. Economic proportioning must be a secondary, although still an important, consideration. There are many features of sewage treatment plants, nevertheless, which may be subjected to analysis to determine the most economic proportions. These features may be both structural and hydraulic.

Among other functions economic proportioning has to do with the determination of the most advantageous plant elevations. In this single item of planning there is frequently to be found a signal opportunity for cost saving. There may be one controlling elevation which will represent the greatest overall economy for the project. That elevation should be sought. Any other might involve more pumping, more excavation, more difficult and expensive foundations, less flexibility in operation, or some other costly or undesirable feature.

Effective sedimentation imposes severe depth limitation. Sludge-removal equipment may control the width of settling basins. Lengths must be sufficient to prevent excessive short circuiting. Certain shapes of basins require much more area than others. The economic dimensions of two basins in a single structural unit will usually differ from those of a single unit; and the economically most advantageous dimensions of several basins in a single structural unit will vary from those of a smaller number of basins. Unfortunately, however, the dimensions that will produce the best effluents may not vary in such manner.

One of the most common, and perhaps the best understood, problems of economic proportioning in sewage works design, as well as elsewhere, is that of the determination of the most economic diameter of force mains. In this case, where the volume of sewage or sludge will increase with the growth of the contributing district, the annual costs of pumping should be calculated for various pipe sizes and for various dates throughout the anticipated life of the pipe. The mean minimum cost will define the most economically advantageous diameter. Here again, however, the characteristics of the sewage or sludge must be considered. Pumps and pipe lines most economically proportioned for water may be so small as to become clogged with sewage or sludge. Moreover, the friction factor, due to grease accumulation, may increase with age. The entire subject is assuredly one of great interest and importance.

FREDERIC BASS,[6] M. AM. SOC. C. E. (by letter).—In the voluminous literature on sewage treatment relatively little is found on the economic phase, and for that reason alone this admirable paper is welcome. The author has industriously and painstakingly accumulated a great quantity of data on costs and performances of the larger plants of the United States, and has arranged and correlated them in a manner adaptable to various situations under average conditions.

As the obvious purpose of this paper is to present data that will be of assistance to the engineer in selecting the degree and type of treatment for a particular case, the writer believes that emphasis should be placed on: (1) The need of more extended study of the requirements of each situation; and (2) the effect of local factors that may alter the relative economy of types of treatment, as indicated by the average costs given. The author states (see "Comparison of Various Processes: General"): "Having arrived at what seem to be reasonable basic cost and reduction data for normal conditions, this section of the paper is devoted to a comparison of the various processes, and a discussion of certain factors that affect their relative economy and thus serve to alter the general indications presented in the comparisons." Furthermore (see heading, "Comparison of Various Processes: Miscellaneous Factors Affecting the Comparison"): " * * * 75% [of the plants] are within a range of 20% above or below the estimated curves of costs shown in the curves"; and 61% are within the same range for costs of operation and maintenance. The specific causes of variation from the average are mentioned: Fixed charges, sewage characteristics, seasonal variations in degree of treatment, commodity costs, head available, and design features. However necessary it may be for the designer to be in possession of average over-all costs of construction and operation, it is of prime importance for him to keep in mind the possible variations from the average due to local conditions.

---

[6] Cons. Engr.; Prof. of Municipal and San. Eng., Univ. of Minnesota, Minneapolis, Minn.

The author recognizes that the fundamental economic consideration is the degree of treatment necessary. This most important factor has quite often been given scant attention, particularly in smaller plants. In many cases it is apparent to the engineer that primary treatment only is required for all conditions, or that, on the other hand, continuous secondary treatment is necessary, but there are many cases in which only extended laboratory-controlled observation can determine the degree of treatment required to maintain a given standard in the receiving body of water and the varying degrees of treatment required in a stream of widely fluctuating discharge. The standard may be that of a minimum dissolved oxygen content in the stream alone, or in combination with suspended solids—or, in some cases, in addition, a bacteriological standard. At present there appears to be difference of opinion with respect to dissolved oxygen content standards in the receiving body of water, and until this question is fully answered in each doubtful case, the economic degree and type of treatment cannot be determined. Relatively few designing engineers possess the equipment for making the investigations necessary; the expansion of the services of the U. S. Public Health Service and of State Health Departments in making continuous surveys of sewage-polluted streams and from them establishing definite conditions to be met by treatment plants would, in the end, contribute very greatly to the economic design and operation of all treatment plants. At present (1938) such investigations are limited to the larger cities. Investigations by Federal, State, or by inter-State authorities have the further advantage of treating natural drainage districts as a whole, allotting to each community its proper share of the burden of cost.

As such investigations multiply and are made generally available the primary economic factor of degree of treatment required will tend to become limited within narrower ranges. In the case of the Minneapolis-St Paul plant (to which the author calls particular attention) long and detailed studies of the Mississippi River were made under the direction of the late J. A. Childs, M. Am. Soc. C. E., but the uncertainties in predicting the effect of some of the factors, particularly the rate of oxygen absorption by sludge deposits, required a considerable factor of safety to assure the required dissolved oxygen content in the river after the plant was in operation. If more extended investigation resulting in more firmly established and generally accepted technique had been available at that time, more precise interpretation of the situation would have been possible. From the economic standpoint, the decision as to the minimum dissolved oxygen content to be maintained in the receiving stream, whether it be 2 ppm or 4 ppm is vitally important. Accumulation of further data that will throw light on this factor will be of great value. Having such data, all the information in this paper may be used to its fullest extent.

One of the noticeable characteristics of the data presented is that practically all of them are of the last decade (1927–38) and many of the last two or three years. Even during the period when the Minneapolis-St. Paul plant was being designed, new and important information concerning developments in all types of treatment was forthcoming. In 1928, a trickling filter plant would have been designed and, in 1933, an activated sludge plant. The development of the chemical treatment process and effluent filter in this period contributed to the principle of flexibility in degree of treatment as required by the fluctuations of stream flow.

The feature of this paper showing the costs of operating secondary processes for fractions of the year suggests emphasis upon the economic values of this principle and that other combinations than those mentioned may be suitable in certain cases. In Table 16 the cost of effluent filters (if regarded as a secondary process) might be added, as such filters appear to be available in connection with plain sedimentation when that is not at all times sufficient, and when higher degrees of treatment attainable by other secondary processes are not required. From the data given of such filters, it appears that with plain sedimentation, 31 ppm suspended solids and 21 ppm B.O.D. would be removed by filtration. These values must be added to the 56% of suspended solids and 36% B.O.D. removed by plain sedimentation to obtain the over-all removal. From the costs of filtration shown in Table 18, on a plant of 100 mgd capacity, the fixed charges at 6% would be $24 000 and the operation and maintenance cost, $25 550, a total of $49 550.

TABLE 18.—ADJUSTED COSTS OF FILTRATION

Sewage treated, in million gallons per day	Construction cost, in dollars per million gallons per day	Operation and maintenance costs, in dollars per million gallons
20	4 500	0.95
50	4 200	0.80
100	4 000	0.70

Another combination that might be considered is that of short-period aeration (perhaps 2.5 or 3 hr) followed by effluent filters, if and when data are available to show the reductions by filtration of the suspended solids and bio-chemical oxygen demand from the effluent of the secondary settling basins of the activated sludge process.

In the section on trickling filters, the author has given as a basis the costs of construction and operation-maintenance at a rate of 2.0 mgd per acre. He has mentioned the fact that large-scale experiments (at Minneapolis, Minn., and Chicago, Ill.) have used rates as high as 20 and 25 mgd per acre. These experiments have resulted in securing bio-chemical oxygen demand removals from 65% to 75% and, in some cases, more. If, in practice, an average of 70% bio-chemical oxygen demand removal is attained (which seems likely) and a total construction cost of from 50% to 60% of a plant having a capacity of 2 mgd per acre with an operating cost perhaps 5% greater than that of the slower rate plant, values in Table 19, based on costs given in the paper for trickling filters at the lower rate, would apply. A curve might be added to Fig. 1(*b*) based on Table 19 which would appear quite closely parallel to the trickling filter curves, but to the left of them.

Although these last two illustrations of possible combinations cannot be substantiated by costs from actual large-sized installations (in view of the rapid rate at which new processes and combinations of processes are developing under adequate laboratory control) it is in that direction that sanitary engineers may look for advances in the near future.

In treatment plants with capacities of approximately 5 mgd and more, it is reasonably certain that careful and continuous laboratory control will be secured and that the performances cited in this paper will be achieved at the costs indicated. At present, information is necessarily obtained from them. Unfortunately, in considering the smaller plants, which obviously are greater in number, such control and information are lacking in many cases. In these plants the actual performances of the various types are likely to be so variable and to differ so much from their potential performances that not only is economic comparison more difficult, but certain types, because of the need of their more careful operation, due to their sensitiveness to varying conditions, should be eliminated altogether from consideration. In order to secure true economy in sewage treatment in the smaller cities, generally, the engineer must recognize the need for educating the public and its representatives in the value of acquiring necessary data for the correct solution of engineering projects.

TABLE 19.—COST OF HIGH RATE TRICKLING FILTERS

Plant capacity, in million gallons per day	Estimated construction cost	Estimated operation and maintenance	Fixed charges	Total annual cost	Annual cost, in million gallons	Cost; 1% per million gallons per 5-day B.O.D. reduction
10	$ 660 000	$ 31 500	$ 39 600	$ 71 100	$7 110	$0.278
20	1 265 000	52 500	75 900	128 400	6 420	0.251
50	3 025 000	115 500	181 500	297 000	5 940	0.232
100	5 885 000	226 300	353 100	579 400	5 794	0.227

This paper suggests that a great mass of unpublished data on the economic aspect of sewage treatment is existent and that this rapidly advancing science would benefit by its publication.

LABORATORY INVESTIGATION OF FLUME TRACTION AND TRANSPORTATION

By Y. L. Chang,[1] Esq.

With Discussion by Messrs. Hans Kramer, E. W. Lane, Joe W. Johnson, J. E. Christiansen, W. H. Huang, Lorenz G. Straub, Hunter Rouse, and Y. L. Chang.

Synopsis

This paper describes a laboratory investigation of the problems of flume traction and transportation. Authoritative literature on the subject is also reviewed. Although the experiments are not—and cannot be expected to be—of the high accuracy obtainable in some classes of laboratory work, it is hoped that the results, when suitably corrected and refined, will provide a close guide to a scientific conclusion.

The subject is presented under three main headings: Part I is concerned principally with the tractive force required to cause initial movement of débris; the laboratory investigation by the writer is described in detail, an equation for critical tractive force is presented, and the results obtained by other investigators are tabulated and shown to conform generally to the same equation. Part II deals with the laws of transportation by traction, and Part III, with the laws of transportation by suspension. In each case the writer's experiments are reviewed briefly, while the major part of the presentation consists of theoretical analyses and discussions of the work of other experimenters. Formulas are suggested for making rough estimates of the traction load and the suspended load in either natural streams or regularly shaped channels. The nomenclature is summarized in the Appendix.

This paper is an abstract of a thesis[2] entitled "Hydraulics of Flume Traction and Transportation".

PART I.—FLUME TRACTION

The first part of the investigation was directed to determining the critical tractive force for a series of uniform sands of various sizes, and to studying the relation between the variables involved.

Note.—Published in November, 1937, *Proceedings*.

FIG. 1.—GENERAL ARRANGEMENT OF TESTING APPARATUS

Description of Apparatus

The laboratory flume and appurtenances are shown in Fig. 1. Three different arrangements were possible: (1) A uniform channel, 18 ft long and 12 in. wide; (2) a uniform channel, 18 ft long and 6 in. wide; and (3) a uniform channel, 12 ft long and 12 in. wide, followed by a 6-ft length of channel converging to a width of 6 in. at its down-stream end. The convergent section was provided in order to locate more exactly the point (and, hence, the velocity) at which movement commenced. The point-gage, Pitot tube, and templet for smoothing the bed were arranged to slide on rails on top of the flume.

The point-gage could be read to 0.005 in. The drop in water-surface elevation from point to point along the flume was measured accurately by means of a toluene differential gage, inclined at an angle of α from the horizontal. This arrangement of the apparatus produced a magnification of 46 to 1 when $\alpha = 10°$, and readings were taken with a traveling vernier microscope (Fig. 2) reading to 0.01 mm. Proper corrections were made for temperature, which was observed on a mercury thermometer in contact with the gage.

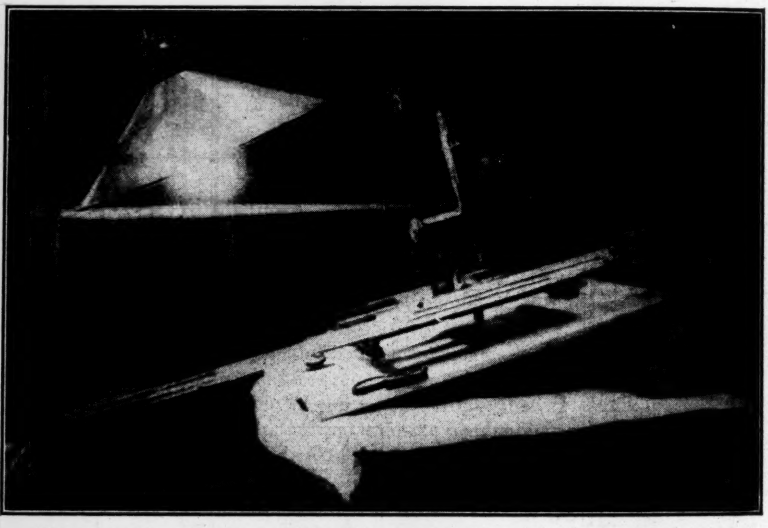

Fig. 2.—Toluene Differential Gage (Inclined) with Traveling Vernier Microscope

The water discharge could be measured either by means of a diaphragm in the feed-pipe or, volumetrically, in the tank at the down-stream end of the flume. Short match sticks, weighted to float vertically, were used for observations of surface velocity, and a Pitot tube connected to a toluene gage provided accurate readings of sub-surface velocities at any desired point.

Procedure

A special feature of the present experiment is that the bed of the flume was horizontal, instead of inclined to the same slope as the water surface.

The latter arrangement is theoretically sound, by the reasoning of uniform flow and parallel tractive force, but the necessity for it is doubtful. In model experiments the slope should never be sufficient to produce shooting flow; the permissible limit, for depths commonly used, is about 0.002. The actual velocity required to initiate movement of the samples used in the present experiments was much smaller than that corresponding to the limiting slope, the average value being about one-fourth of it. To mold the bed exactly to such a slope is very difficult, even with accurate apparatus, and, for smaller slopes, it is entirely impracticable.

With the bed horizontal, it would be possible to correct to the condition of uniform flow by subtracting the loss of potential head due to acceleration of flow, from the observed drop of surface level. However, in the present experiments, with a smooth unriffled bed, this loss never exceeded 0.0002 ft, and, being smaller than the deviation of the static readings from the differential gage, was neglected. Over a riffled bed, any such correction is meaningless, for the surface waves are of the same order of amplitude as the riffles.

In beginning a test run, the bed material was placed in the flume, wetted thoroughly, and made perfectly level and smooth by means of the brass templet and a trowel. Water was then introduced very gradually so as not to disturb the smooth bed (even tiny surface waves may produce riffles especially in shallow depths). After the flume had filled sufficiently, the test run was begun, the depth of flow being controlled by the movable weir plate at the end of the settling tank, and by the valve in the feed-pipe.

When sand movement began, the water discharge was kept constant for a while to make sure that the movement was due to the drag of the flow rather than to local irregularities. Then the flow was increased a little to generate stronger movement of the bed. This procedure was continued until data for "general movement" were obtained. (The term "general movement" applies to that condition in which grains of mean diameter are in motion so frequently that the numbers are not countable. Such motion should be general, not local. It is not strong enough to affect bed configuration and does not result in transportation of an appreciable quantity of material.)

In the uniform channel the slope of the water surface can be measured directly by the differential gage; in the convergent section the slope varies at different points, and can be determined more accurately by calculation, taking into account the different roughnesses on the bed and the sides.

Mechanical Properties of Test Samples

In all, twelve commercially sieved samples were tested in the flume, each sample consisting of grains of more or less uniform size. The average grain diameter varied from 8.090 mm for the coarsest sample to 0.134 mm for the finest. The principal mechanical properties are listed in Table 1.

The method of determining the grain diameters requires some explanation. For each sample, 150 particles were selected arbitrarily and examined under a microscope. The two diameters, D_1 and D_2, are those lying in the plane parallel to the horizontal glass, and were measured during this examination. For the coarsest materials, D_1 and D_2 were measured by projecting the images of the grains on to a screen. The diameter, D_3, is the vertical dimension of the grain. In general, the shortest of the three, D_3, cannot be measured under the microscope, and must be computed from the grain volume, as measured by the displacement of a definite number of grains in water. For this computation, the general shape of the grains must be assumed. Each sample appeared to be composed of grains of two general shapes, which may be designated as "spherical" and "cubical," respectively. An examination of about 50 grains by eye permitted an approximate determination of the relative number of grains of the two shapes. The demarcation is not definite, and the estimate in Column (9), Table 1, is rough, but it does permit the computation with reasonable accuracy of D_3, as well as of the mean diameter, D, and the ratio, o, of the longest to the shortest diameter. For fine grains the volume of which was not measurable, D was assumed equal to the mean of D_1 and D_2, and o was taken as $\frac{D_1}{D_2}$.

TABLE 1.—MECHANICAL PROPERTIES OF TEST SAMPLES

† Composed of black and white particles.

‡ Separate analysis of the white particles of the pumice sample. About 95% of the pumice particles transported, and collected in the settling tank, and practically all the pumice particles in suspension, were white.

The uniformity modulus, M, has been proposed by Hans Kramer,[3] M. Am. Soc. C. E., as a convenient expression for the distribution of sizes of the particles in a sand mixture. The uniformity modulus of the samples used in this experiment was not determined, but a rough plotting of the microscopic readings of the grain sizes showed that all samples had nearly the same distribution. They are assumed, therefore, to have the same uniformity modulus.

EQUATION OF VARIED FLOW

As many observations were taken in the convergent channel, application of the principles of non-uniform flow[4] is necessary to evaluate slope and also to study the tractive force. The general expression for non-uniform flow is:

---

[3] "Sand Mixtures and Sand Movement in Fluvial Models," by Hans Kramer, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 798.

[4] "Hydraulics of Open Channels," by B. A. Bakhmeteff, M. Am. Soc. C. E., N. Y., 1934, p. 24.

$$S = S_0 - \frac{dy}{dx} = \frac{V^2}{C^2 R} - \frac{Q^2}{g B^2 y^3} \frac{dy}{dx}$$

the nomenclature being explained in the Appendix.

For a rectangular section, since $Q = V B y$,

$$\frac{dy}{dx} = \frac{S_0 - \frac{V^2}{C^2 R}}{1 - \frac{V^2}{g y}} \qquad (1)$$

For a horizontal bed, $S_0 = 0$; and reducing to Manning's form,

$$\frac{dy}{dx} = \frac{1}{C^2 R \left[\frac{1}{g y} - \frac{1}{V^2} \right]} = \frac{n^2 V^2}{2.21 R^{4/3} \left[\frac{V^2}{g y} - 1 \right]} \qquad (2)$$

in which C has been replaced by $\frac{1.486 R^{1/6}}{n}$. Further,

$$S = - \frac{dy}{dx} = \frac{n^2 V^2}{2.21 R^{4/3} \left[1 - \frac{V^2}{g y} \right]} \qquad (3)$$

Hence, for any value of V less than $\sqrt{g y}$, the slope of the water surface in the convergent channel can be calculated by the ordinary Manning formula for uniform flow, and divided by the term, $\left[1 - \frac{V^2}{g y} \right]$, to correct for the non-uniform flow condition.

MANNING'S n FOR THE SAMPLES

The value of n for the flume as a whole is a function of n_g (the roughness coefficient of the glass sides) and n_s (the coefficient for the sample composing the bed). It was desired to determine separately the value of n_s.

The Manning formula, with R replaced by $\frac{A}{p}$, may be written,

$$V = \frac{1.486 A^{2/3} S^{1/2}}{(n^{3/2} p)^{2/3}}$$

In the present case, the denominator of the fraction may be equated as follows:

$$n^{3/2} p = n_s^{3/2} B + 2 n_g^{3/2} d \qquad (4)$$

in which d is the depth of flow. Then, if n_g and n are known, n_s can be computed.

There are two methods of determining n_g: (1) Experimentally: Assuming the brass bottom to have the same roughness as the glass, observations on flow through the flume with the sand bed removed will yield the desired value; and (2) by calculation from a derived formula.

J. Allen[5] has derived a formula for the roughness coefficient in terms of the Reynolds number, which reduces to,

$$n = \frac{R^{1/6}}{35.3 \left(\frac{R\,V}{\nu}\right)^{3/40}} \quad \text{.....................} (5)$$

The relation holds provided the bed and sides of the channel are smooth.

Results of Methods (1) and (2) proved to be in reasonable agreement, and gave a mean value for n_g of 0.0103.

In the present experiments, there are two cases of uniform flow and one of non-uniform flow. The corresponding equations for n_s are:

1.—For uniform channel, 1 ft wide:

$$n_s = [(1 + 2\,d)\,n^{3/2} - 2\,dn_g^{3/2}]^{2/3} = [(1 + 2\,d)\,n^{3/2} - 0.00208\,d]^{2/3}$$

2.—For uniform channel, 0.5 ft wide:

$$n_s = [(1 + 4\,d)\,n^{3/2} - 4\,dn_g^{3/2}]^{2/3} = [(1 + 4\,d)\,n^{3/2} - 0.00405\,d]^{2/3}$$

3.—For the convergent channel (any width):

$$n_s = \left[\frac{(B + 2\,d)\,n^{3/2} - 0.00208\,d}{B}\right]^{2/3}$$

This expression is identical to one derived independently by R. E. Horton,[6] M. Am. Soc. C. E. He extended the method to a trapezoidal canal section, for which he gives the equation:

$$n = \left[\frac{n_b^{3/2} + 2\,z\,n_l^{3/2}}{1 + 2\,z}\right]^{2/3} \quad \text{.....................} (6)$$

in which n_b and n_l are the separate values of n for the bottom and the sloping sides, respectively, and z is the ratio of the length of one of the sloping sides to the width of the bottom. This formula is particularly applicable to natural canals with different roughness of bed and sides.

Values of n_s for the twelve test samples are given, with other pertinent data, in Table 2.

Relation Between Manning's *n* and Size of Particles

Manning's equation is dimensionally sound only if the friction does not depend upon viscosity (that is, only if the turbulence is fully developed) and n has the dimension of $(\text{length})^{1/6}$. It will be shown later that the Chezy coefficient is equal to $\left(\frac{g}{\kappa}\right)^{1/2}$, in which g is the acceleration of gravity and κ, the coefficient of skin friction, a dimensionless factor. Hence, C is of the dimension, $\frac{(\text{length})^{1/2}}{(\text{time})}$. Expressing Manning's n in terms of C, $n = \frac{1.486}{C} R^{1/6}$. Since n is independent of time, the constant, 1.486, must be of the same dimensions as C; hence, n is of the dimension, (length)$^{1/6}$. The experimental Equation (5) gives the same result.

* Experiment done in a uniform channel, 1 ft wide.

Strickler has proposed the equation,

$$n = 0.0150\,D^{1/6} \quad \text{.......................(7)}$$

in which D is the median diameter of the grains of the surface layer, in millimeters. Logarithmic plotting of the values of n for the samples shows exceedingly good coincidence to Equation (7). The equation of the straight line best fitting the plotted points (Fig. 3) is

$$n = 0.0166\,D^{1/6} \quad \text{.......................(8)}$$

D in this case being the mean diameter of the bed material, in millimeters. The difference in the value of the constant is probably due to the different geometrical shapes of the grains tested.

AVERAGE TRACTIVE FORCE

For conditions of uniform flow at depth, d, the tractive force per unit area opposed to the bed resistance is

$$T = w\,S\,d \quad \text{.......................(9)}$$

The expression[3] presupposes uniform flow and infinite width of channel. Referring to Fig. 4, the total tractive force in an irregular channel is

$$\Sigma\, T = T_1 + T_2 + T_3 + \cdots = w\, S\, (d_1\, p_1 + d_2\, p_2 + d_3\, p_3 + \cdots) = w\, S\, A$$

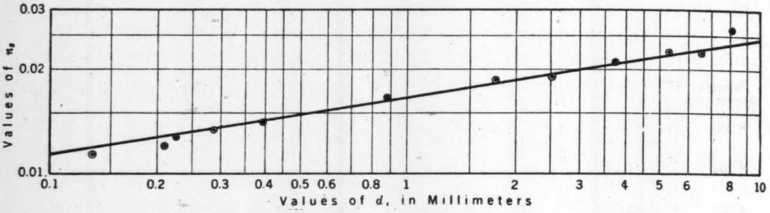

FIG. 3.—RELATION BETWEEN MANNING'S n AND MEDIAN DIAMETER OF SAND PARTICLES COMPOSING BED OF EXPERIMENTAL FLUME

and the average tractive force per unit area becomes,

$$\overline{T} = \frac{w\, S\, A}{p} = w\, S\, R \quad \text{(10)}$$

The average unit tractive force in a rectangular flume should be

$$\overline{T} = w\, S\, d\, \frac{B}{B + 2\, d} \quad \text{(11)}$$

According to Schoklitsch[7] an additional coefficient is required for channels in which the ratio of width to depth is less than 30. In such a case the average tractive force becomes, $\overline{T} = \frac{30}{32}\, w\, S\, d$, which is about 6% smaller than $w\, S\, d$. Schoklitsch[7] has suggested a similar, but more complete formula,

FIG. 5.—TRACTIVE FORCE IN ACCELERATING FLOW

$$T = \alpha\, w\, S\, d \quad \text{(12)}$$

in which $\alpha = \dfrac{1 + \dfrac{d}{B}\, i}{1 + \dfrac{2\, d\, n_l}{B\, n_b}\sqrt{1 + i^2}}$, in which n_b and n_l are, respectively, the Manning n for the bottom and the sides, and i is the horizontal over the vertical of the sides. When $n_b = n_l$ and $i = 0$, $\alpha = \frac{B}{B + 2\,d}$, which is identical to Equation (11).

EFFECT OF NON-UNIFORM FLOW ON TRACTIVE FORCE

Assume the flow to be non-uniform but accelerating (the flow in the flume with horizontal bed is of this kind) in a channel of infinite width (Fig. 5). The change in energy between two sections may be expressed as follows: Increase of kinetic energy + work done in overcoming bed resistance = decrease in potential energy.

For a column of water of unit volume:

$$w\,\frac{y}{g}\,\tfrac{1}{2}[(V + dV)^2 - V^2] + T\,dx = w\,y\,\frac{\sin\alpha + \sin\alpha_0}{2}\,dx \ldots\ldots (13)$$

in which T is the tractive force on the bed, assuming that all frictional loss is due to bed resistance. Neglecting higher orders of the derivative than the first and reducing, Equation (13) becomes,

$$T = \left[w\,y\,\frac{\sin\alpha + \sin\alpha_0}{2} - \frac{w\,y\,V}{g}\,\frac{dV}{dy}\,\frac{dy}{dx} \right] \ldots\ldots\ldots\ldots (14)$$

Taking $V = \frac{q}{y}$, in which q is the discharge per unit width of the channel, $\frac{dV}{dy} = -\frac{q}{y^2} = -\frac{V}{y}$. Also, $-\frac{dy}{dx} = \sin\alpha_0 - \sin\alpha$; and

$$T = \left[w\,y\,\frac{\sin\alpha + \sin\alpha_0}{2} + w\,\frac{V^2}{g}\,(\sin\alpha - \sin\alpha_0) \right] \ldots\ldots\ldots (15)$$

For a sloping bed with uniform flow, $\sin\alpha = \sin\alpha_0 = S$:

$$T = w\,S\,y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

For accelerating flow, $\alpha > \alpha_0$; for decelerating flow, $\alpha_0 > \alpha$. For accelerating flow on a horizontal bed, $\sin\alpha_0 = 0$:

$$T = w\,S\left(\frac{y}{2} + \frac{V^2}{g}\right) = \frac{w\,S}{2}\left(y + 4\,\frac{V^2}{2\,g}\right) \ldots\ldots\ldots\ldots (17)$$

therefore, for high depth with comparatively small velocity, the tractive force on a horizontal bed is one-half that on a sloping bed with the same inclination of the water surface. In case $\sin\alpha_0 = -\sin\alpha$, that is, when the bed has an adverse surface slope, there is only a tractive force by the velocity head, namely, $w\,S\left(4\,\frac{V^2}{2\,g}\right)$.

SUGGESTED EQUATION FOR CRITICAL TRACTIVE FORCE

The critical tractive force, T_0, has been defined as that tractive force which brings about general movement of the average grains of the bed material. This force, which is constant for a certain material, is not determined by either d alone or S alone, but by a constant product, $w\,S\,d$. Considering the tractive force as a function of the mechanical properties of the bed material, it can be written, $T_0 = F$ (grain size, grain distribution, grain form, apparent weight per unit volume in water) $= F\,(D^x\,M^{-1}\,n^{\alpha}\,\rho_e^{y})$ in which Manning's n is assumed to be a function of the size and shape of the grains. It has been shown by Kramer[3] that tractive force is inversely proportional to M, which is a pure numerical ratio. Victor L. Streeter,[8] Jun. Am. Soc. C. E., has suggested that the coefficient of roughness varies directly with the depth and slightly with the interval of the grooves; for larger and more irregularly shaped grains, the grooves on the surface of the material would be expected to be deeper and larger. Therefore, it can be assumed that n, having a dimension of $(\text{length})^{1/6}$, takes the place of $(D\,o)^{1/6}$. By the method of dimensional analysis the following exponentials may be equated: $1 = y$; and $-1 = x - 2\,y + \frac{\alpha}{6}$. From Manning's formula, however, the tractive force, T, is proportional to n^2; therefore, $T_0 = c\,D^{2/3}\,\rho_e\,n^2\,M^{-1}$, in which c is a constant, and if n is assumed proportional to $(D\,o)^{1/6}$,

$$T_0 = \frac{c\,D\,\rho_e\,o^{1/3}}{M} \qquad (18)$$

For uniform, equal sized grains of material, $M = 1$, and for spherical grains, $o = 1$, and the formula reduces to

$$T_0 = c\,\rho_e\,D \qquad (19)$$

which is dimensionally correct.

Critical Size of Sand for Critical Tractive Force Relationship

Table 3 shows in detail the observations made on a typical sample to determine the critical tractive force, and Table 4 summarizes the results of tests on all samples. In Fig. 6, the mean values of T_0 are plotted logarithmically against the values of $\rho_e\,D\,o^{1/3}$, M being assumed to be unity for uniform material or a constant for uniform distribution. It will be noted that for sand of a larger size than No. 6198, a line inclined at 45° to the X-axis joins up the points smoothly; for sand less than that size the points are better fitted by a line inclined at approximately 26.5 degrees. This fact indicates that there is a critical value of the function, $\rho_e\,D\,o^{1/3}$, above which it is directly proportional to the critical tractive force, and below which it is proportional to the square of the latter quantity. It happens that these two lines intersect at the value of T_0 for $\rho_e\,D\,o^{1/3} = 1.0$. Expressed symbolically,

$$T_0 = 0.0175 \left[\frac{\sigma - \rho}{\rho}\,D\,o^{1/3} \right]^{\beta} \qquad (20)$$

in which $\beta = 1$ for $\frac{\sigma - \rho}{\rho}\,D\,o^{1/3}$ greater than 1, and $\frac{1}{2}$ for $\frac{\sigma - \rho}{\rho}\,D\,o^{1/3}$ less than 1.

Sand α	1.520	0.134	1.37	1.111	0.226	0.0075	0.00395

For ordinary quartz sand, $\sigma = 2.65$; $\rho = 1$; and $o = 1.75$. Hence, the size of sand corresponding to the critical value of the function is approximately 0.5 mm. For spherical grains, $o = 1$; therefore, $D = 0.6$ mm (approximately). In other words, for ordinary quartz sand grains larger than 0.5 to 0.6 mm in mean diameter, the critical tractive force is proportional to $\rho_s\, D\, o^{1/3}$; for smaller sands it is proportional to the square root of that function.

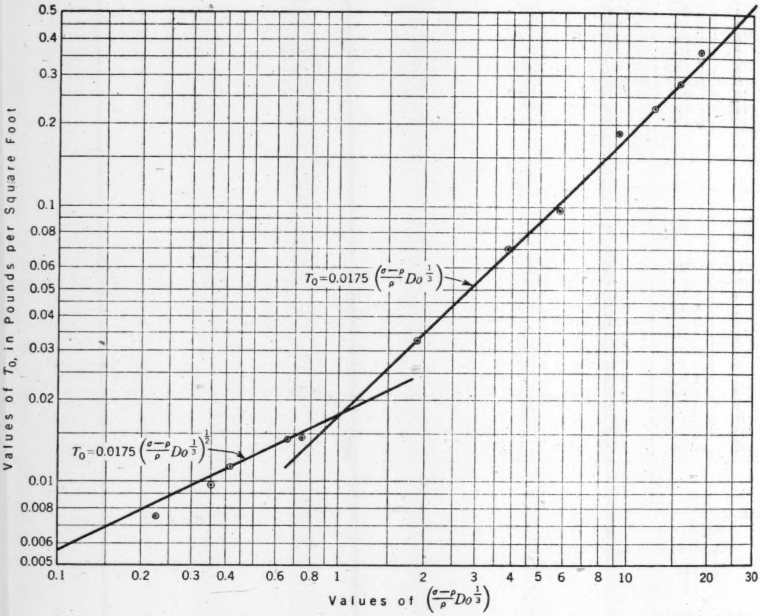

FIG. 6.—CRITICAL TRACTIVE FORCE (CHANG EXPERIMENTS; HORIZONTAL BED; *M* ASSUMED UNITY)

Pertinent experimental data from all available sources are summarized in Table 5, and plotted in Fig. 7, with the uniformity modulus taken into account. (The values of o are not available and are considered unity.) To reduce to the condition of uniform flow, the value of T_0 of the writer's experiment should be reduced to one-half; but here, instead, the numerical values of $(\rho_s\, D\, o^{1/3})$ have been doubled to correspond to a uniform modulus of 0.5. Here, again, the results suggest the existence of a critical size of sand with respect to the critical tractive force relationship, although the demarcation of the two lines is, in this case, by no means distinct. A reason for this lack of definition will be advanced subsequently.

The two equations for T_0, represented by the lines on Fig. 7, are:

For $\left[\frac{\sigma - \rho}{\rho} \frac{D}{M}\right] > 2.0$:

$$T_0 = 0.00450 \left[\frac{\sigma - \rho}{\rho} \frac{D}{M}\right] \qquad (21a)$$

† o assumed unity for others than the writer's results.

and for $\left[\frac{\sigma - \rho}{\rho}\frac{D}{M}\right] < 2.0$:

$$T_0 = 0.00635 \left[\frac{\sigma - \rho}{\rho}\frac{D}{M}\right]^{1/2} \dots\dots\dots\dots\dots\dots (21b)$$

At the intersection, $\frac{\sigma - \rho}{\rho}\frac{D}{M} = 2.0$; hence, for $M = 0.5$, $D \sim 0.5$ mm. If the value of $M = \frac{1}{2}$ be substituted into the equations they become identical:

$$T_0 = 0.00900 \left[\frac{\sigma - \rho}{\rho} D\right]^{\beta} \dots\dots\dots\dots\dots\dots (21c)$$

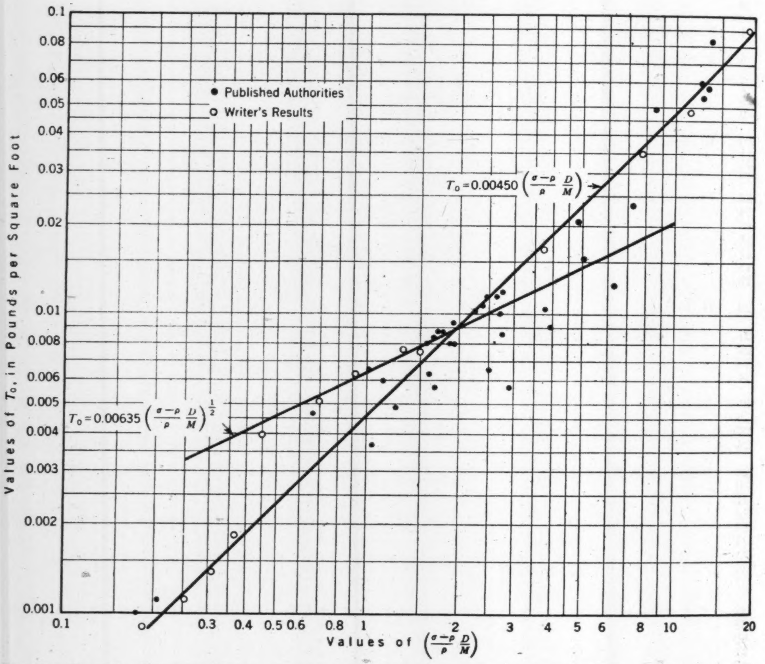

FIG. 7.—CRITICAL TRACTIVE FORCE (DATA FROM VARIOUS SOURCES; *o* ASSUMED UNITY; PLOTTING ADJUSTED TO $M = \frac{1}{2}$)

The numerical coefficient in Equation (21*c*) is just about one-half that in Equation (20), showing that the tractive force needed to move débris on a sloping bed parallel to the water surface is only one-half that needed on a horizontal bed. It also indicates that the uniform modulus, *M*, has practically nothing to do with the critical tractive force, and could be omitted.

The equation suggested by Kramer for critical tractive force is,

$$T_0 = 0.00339 \left[\frac{\sigma - \rho}{\rho}\frac{D}{M}\right] \dots\dots\dots\dots\dots\dots (22)$$

Equation (22) has been modified by the United States Waterways Experiment Station[9] to

$$T_0 = 0.00595 \left[\frac{\sigma - \rho}{\rho} \frac{D}{M} \right]^{0.5} \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

It is clear that both formulas are derived from the same data; then, if both are right, there must be a criterion separating the available data into two sets satisfied, respectively, by Equations (22) and (23). In this connection it is interesting to note the following quotation from the Station's report:[10]

> "There must be some limiting size of particle at which the larger size no longer moves first, and above which the finer materials are the first to be placed in motion. While no data were recorded in these experiments which would tend to locate this limiting size, it is believed that its value is in the vicinity of 0.6 mm."

In a paper by Morrough P. O'Brien,[11] Assoc. M. Am. Soc. C. E., the existence of such a criterion has also been outlined.

TURBULENCE AS AN INTERPRETATION

Dimensionally, the idea that the critical tractive force is proportional to $\rho_e \, D \, o^{1/3}$, taking o as a dimensionless ratio, is correct. In case it is proportional to $[\rho_e \, D \, o^{1/3}]^{1/2}$, the coefficient by which the function is multiplied will no longer be dimensionless. The turbulence of the flow is suggested as an explanation of this variation. The action of the tractive force on the bed material is equivalent to the motion of a fluid resisted by a tangential stress at the wall in a channel or in a pipe. It is reasonable to presume that this unit stress, T_0, will be a function of the depth, d (or hydraulic radius, R), density, ρ, viscosity, μ, and mean velocity, V; that is, $\tau_0 = C_1 \, d^x \, \rho^y \, \mu^z \, V^k$. By dimensional analysis, the form of this function[12] is found to be

$$\tau_0 = C_1 \, d^{k-2} \, \rho^{k-1} \, \mu^{2-k} \, V^k \ldots\ldots\ldots\ldots\ldots\ldots (24)$$

For laminar flow, $k = 1$, and is constant because the flow is independent of the roughness of the wall. For turbulent flow, the value of k varies from 1.75 for extremely smooth channels to a maximum of 2 for channels which are rough. For $k = 1$, $\tau_0 = C_1 \frac{\mu}{d} V = K_1 \, V$, and for $k = 2$, $\tau_0 = C_1 \, \rho \, V^2 = K_2 \, V^2$. These relations are sketched logarithmically in Fig. 8, and can be expressed in the form, $\tau_0 = K \, V^\alpha$, in which $\alpha = 1$ or 2.

Tractive force in turbulent flow varies with the square of the mean velocity, whereas tractive force in laminar flow varies directly with the mean velocity; consequently, if it is reasonable to presume that the tractive force in turbulent flow is a certain function of the sand, then the tractive force in laminar flow will be the square root of the same function, because in such flow the function of sand is equivalent to the reaction of the shearing stress due to velocity. Therefore, in the general equation,

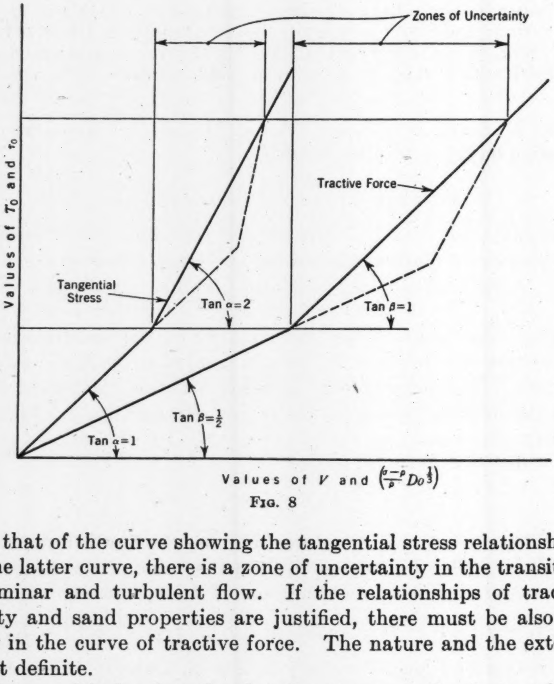
[12] "Modern Conceptions of the Mechanics of Fluid Turbulence," by Hunter Rouse, Assoc. M. Am Soc. C. E., *Proceedings*, Am. Soc. C. E., January, 1936, p. 21.

$$T_0 = C\left[\frac{\sigma - \rho}{\rho} D\, o^{1/3}\right]^{\beta} \quad\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

in which C is a constant, the experimentally determined values of $\frac{1}{2}$ and 1 for β appear to have a rational justification. Equation (25) is also plotted in Fig. 8. The discontinuity of the curve is here assumed to occur at the same ordinate as that of the curve showing the tangential stress relationship. With regard to the latter curve, there is a zone of uncertainty in the transition region between laminar and turbulent flow. If the relationships of tractive force with velocity and sand properties are justified, there must be also a zone of uncertainty in the curve of tractive force. The nature and the extent of this zone are not definite.



Zones of Uncertainty

Tan β=½
Tan α=1
Values of T_0 and τ_0
Values of V and $\left(\frac{\sigma-\rho}{\rho} D o^{\frac{1}{3}}\right)$

Fig. 8

At the lower critical point, the shearing stresses in laminar and turbulent flow are identical,

$$\frac{\tau_s}{\tau_t} = \frac{\dfrac{2\mu}{R} V}{\dfrac{f}{4}\rho\dfrac{V^2}{2}} = \frac{16}{f}\,\frac{\mu}{V\,R\,\rho} = \frac{16}{f}\,\frac{1}{\mathbf{R}} = 1$$

Assuming 0.01 to be the average value of f, the roughness factor, in the experiment, $\mathbf{R}$ = 1 600; while Allen[5] gives 1 400 as the lower criterion. The upper criterion is uncertain; according to the writer's experiment it may be as much as ten times the value of the lower criterion. (As shown in Fig. 8, the zone of uncertainty on the curve for sand properties is considerably larger than that on the curve for velocity.) The same problem may be explained from another point of view by the theories of frictional drag given in hydro-mechanics.[13]

SUMMARY: PART I

(1) In the convergent channel the water surface slope can be calculated by Equation (3).

(2) When the glass-sided flume used in the writer's experiments has bed material leveled on the bottom, Manning's n_s for the sand can be computed by,

$$n_s = \left[\frac{(B + 2\,d)\;n^{3/2} - 0.00208\,d}{B} \right]^{2/3}$$

assuming that Manning's n_g for the sides of the flume is 0.0103.

(3) The relationship between Manning's n and the mean diameter, D, in millimeters, of the grains is well expressed by Equation (8).

(4) For channels in which the ratio of width to depth is less than 30, Equation (12) may be used to find the tractive force on the bottom of either rectangular or trapezoidal sections.

(5) Water flowing at relatively low velocity in a deep channel with horizontal bed exerts a tractive force on the bottom equal to approximately one-half that exerted in uniform flow. In other words, the resistance to motion of particles on a horizontal bed is nearly double their resistance on a sloping bed having the same inclination as the water surface.

(6) A complete formula for the critical tractive force in terms of the mechanical properties of the sand is Equation (25).

(7) There is a critical size of sand at which the power index theoretically changes suddenly. For quartz sand the critical mean diameter of grain is about 0.5 mm. Turbulence of flow best explains this criterion.

PART II.—TRANSPORTATION BY TRACTION

PROCEDURE

The experiments on transportation by traction were performed in the flume $\frac{1}{2}$ ft wide. Damp material was placed on the bed and leveled. Water was then admitted gradually, to the desired depth; and the flow was adjusted to a condition just above that causing general motion. The period for measuring sand discharge—that is, the time between inserting and withdrawing the collecting bucket—was chosen to be nearly that during which a constant rate of sand movement prevails. For small sand discharges a long period is desirable for the sake of accuracy. For greater discharges the period should be as short as possible, since the surface of the bed changes its form from instant to instant. The dry weight of the collected sand, divided by the measuring period, gives the rate of transportation, G.

The sand was fed automatically, but not accurately. A box, 18 in. by 6 in. by 6 in., filled with the sample material was supported on a rotating shaft connected directly to a $\frac{1}{4}$-hp motor the speed of which could be roughly controlled by a resistance composed of lamps. In the middle of the box there was a baffle-plate that could be moved vertically by screws. The rate of discharging the sand, therefore, could be approximately adjusted by the opening of the baffle-plate, through which the sand was sliding. The criterion to adjust the feeding, however, was based only upon the visual observation of the movement of the sand in the channel.

---

[13] "Applied Hydro- and Aeromechanics," by L. Prandtl and O. G. Tietjens, N. Y., 1934, p. 86.

The depth measured was in all cases the depth to the original smooth bed surface. Slope measurements were made as in Part I. With the higher flows, however, more trouble was experienced in attaining a stable reading. As soon as riffles developed, the differences of readings on the differential gage increased suddenly, and thereafter continued to increase throughout the run. This means that the roughness of the bed was increasing constantly from the time the riffles were formed, other factors being considered almost unaltered. However, the exact rate at which the slope varied is unknown. The mean value of several slope observations, taken desirably at equal time intervals, was assumed to represent the average condition during the run. The length of time of collection varied from 15 min to 1 hr, depending mainly on the intensity of movement. During each run, at least two measurements of water discharge were taken, most of them directly from measuring tank. Types of flow could be easily distinguished with light on the opposite side of the glass flume.

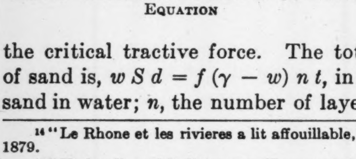
Observations on sand movement and riffle development were carefully noted at different stages. Riffles usually appeared first on the bed at the two ends of the channel, indicating disturbances in those regions, and at isolated points where there were irregularities of flow. Their formation could not be controlled.

DU BOYS' FORMULA

The formula originally derived by du Boys[14] in 1879 is of the form:

$$G = \psi\, T\, (T - T_0) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

in which T is the unit tractive force on the bed; T_0 is the critical tractive force required to initiate general movement; and ψ is a function of the size, etc., of the sand grains. Equation (26) can be written in many other forms by means of Manning's formula.[15] The derivation of Equation (26) was based upon the assumption that sand is moved in layers subject to uniform tractive force, and that the velocity gradient in the moving sand layers is linear. The coefficient of friction of sand in water is also considered constant. According to Fig. 9, the sand does not move at the layer subjected to the critical tractive force. The total tractive force consumed per unit area of sand is, $w\, S\, d = f\, (\gamma - w)\, n\, t$, in which f is the coefficient of friction of the sand in water; n, the number of layers of sand, which depends on the tractive



Linear Velocity Gradient of Sand

$v=0$
Region Not Affected by Tractive Force

FIG. 9.—CONDITIONS ASSUMED IN DU BOYS' EQUATION

force and the sand properties; and t, the thickness of each layer. The rate of sand transportation is, therefore,

---

[14] "Le Rhone et les rivieres a lit affouillable," par P. du Boys, *Annales des Ponts et Chaussées*, Vol. 2, 1879.

[15] "Hydraulic and Sedimentary Characteristics of Rivers," by L. G. Straub, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, 1932.

$$G = t\,w\,[0 + v_0 + 2\,v_0 + 3\,v_0 + 4\,v_0 + \cdots (n-1)\,v_0] = n\,(n-1)\,\frac{w\,t\,v_0}{2}$$

No layer will be moved on which the force is less than the critical tractive force required to overcome the frictional resistance of the bed; therefore, $T_0 = f\,(\gamma - w)\,t$. Hence, $n\,T_0 = w\,S\,d$, and $n = \frac{w\,S\,d}{T_0} = \frac{T}{T_0}$, so that,

$$G = \frac{w\,t\,v_0}{2}\,\frac{T}{T_0}\left(\frac{T}{T_0} - 1\right) = \frac{w\,t\,v_0}{2\,T_0^2}\,T\,(T - T_0) = \psi\,T\,(T - T_0) \ldots\ldots (27)$$

Using Chezy's equation, $V = C\sqrt{S\,d}$,

$$G = \psi\,w^2\,\frac{V^2}{C^2}\left(\frac{V^2}{C^2} - \frac{T_0}{w}\right) \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

Equation (28) indicates that transportation of sand will not occur until $V > C\sqrt{\frac{T_0}{w}}$; thereafter, the rate of transportation will be approximately proportional to the fourth power of the velocity.

The foregoing derivation applies only to the case in which materials are being dragged on a smooth bed; load due to saltation, which is closely associated with the formation of riffles, is not included. Although the derivation is not very sound, the resulting expression checks well with most experimental formulas, and is satisfactory for estimating sand movement in natural streams.

SAND MOVEMENT IN TERMS OF ADVANCE OF RIFFLES

The foregoing discussion applies only to a smooth bed. For a riffled bed, a better interpretation is not yet practicable.

In this paper, the velocity of sand movement is considered to be the same as that of the progression of the riffles. Of course, this assumption is only applicable in the velocity range in which the riffles are progressing in a downstream direction. The plotted results (Fig. 10) of the experiment, although the points are considerably scattered, could still indicate the following relation between the advancement of riffles and the velocity of the flow:

$$v_r = [0.000125 \text{ to } 0.001085]\,V^5 \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

both velocities being in feet per second. (The inclination of the lines is not absolute, because of the scattering of the plotted points, but they are approximately consistent to one another.) It is interesting to compare these results with those of Owens and Deacon.[16] The former gives $G \propto V^6$, whereas the latter indicates $G \propto V^4$. According to Gilbert's[17] observations on natural streams the power of V is much less than 6. His formula, based on flume tests, is, however, of the form $G \propto V^4$. Such deviation could probably be attributed to the different size of flume used.

---

[16] "The Settlement and Transport of Sand in Water," by J. S. Owens, *Engineering*, 1912.

[17] "The Transportation of Débris by Running Water," by G. K. Gilbert, *Professional Paper 86*, U. S. Geological Survey, 1914.

It is observed that saltation is strongest when the riffles are the largest. Very roughly it can be set forth, that,

$$G \propto [(\text{height of riffle})^{\alpha} \times (\text{velocity of riffle})^{\beta}]$$

If it may be assumed that the size of a riffle, ξ, is equivalent to that of a grain,

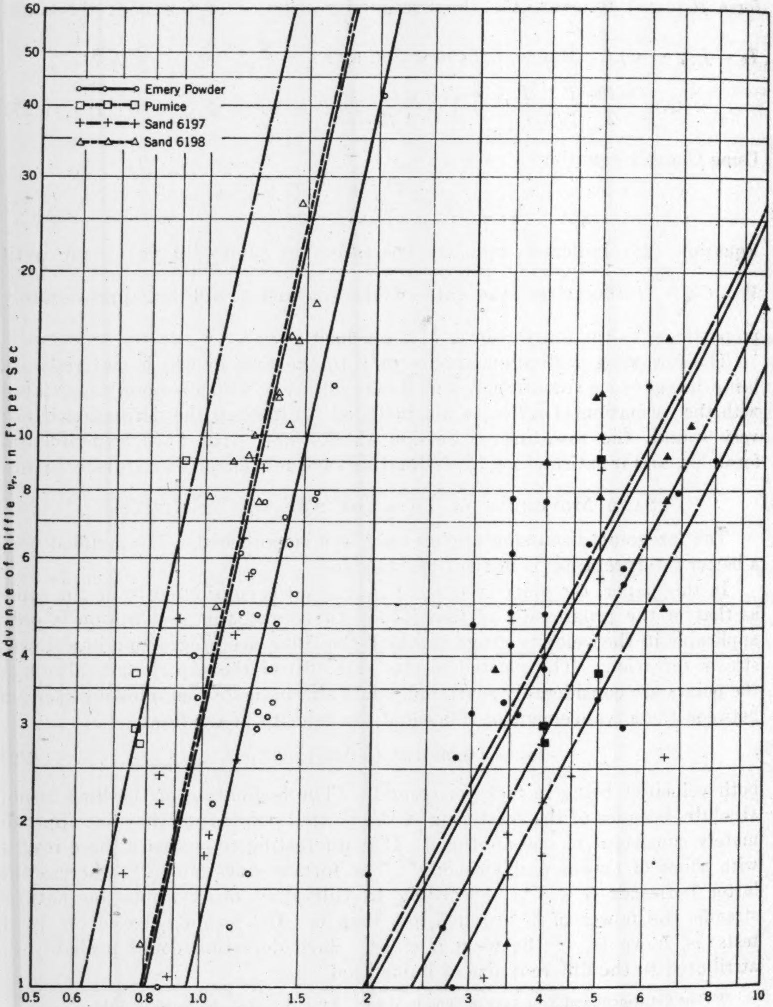

FIG. 10.—ADVANCE OF RIFFLES

and, consequently, that Manning's n is a direct measure of the size of the riffle, then the quantity of sand moved must be also a function of the size of the riffles. The United States Waterways Experiment Station found[10] also that the size of the riffles increased with the percentage of fine material in the mixture; but, obviously, the rate of transportation of a finer mixture is greater unless cohesion comes appreciably into effect. Observations[3] on the Rhine indicate that there is a general increase in the value of Manning's n with an increase in bed-load movement. It has been shown that Manning's n is dimensionally a function of the size of the particles to the one-sixth power. Actual plottings (as in Fig. 11) of the relation of G and n show that G is proportional to n^6, indicating that the exponent, α, should be unity. The deviation of points at higher values of n is due to the restraining effect of the narrow flume; that is, the narrowness limits of the development of larger riffles. When β is also unity, as assumed, the equation becomes:

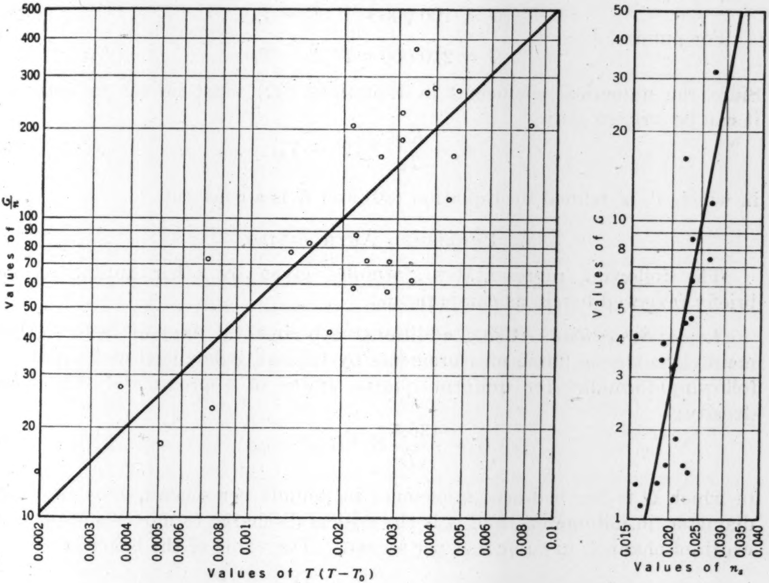

FIG. 11.—DATA ON TRANSPORTATION BY TRACTION: EMERY POWDER

$$G \propto \xi\, V^5 \qquad (30)$$

Using Chezy's formula for an infinite width of channel,

$$G \propto n^6 \frac{(S\, d)^{5/2}}{n^5} \propto n\, T^{2.5} \qquad (31)$$

The appearance of n in Equation (31) is justified dimensionally by noting that $T \propto n^2$.

EXPERIMENTAL FORMULA

A formula of the du Boys' type appears to fit best the data obtained in the present experiment, although the plotted points are so scattered that no equation will join them closely. When $\frac{G}{n}$ is plotted against $T\,(T - T_0)$ logarithmically, as in Fig. 11, lines with an inclination of 45° evidently satisfy the general requirements. The equations of these lines for three of the bed materials tested, read:

For emery,

$$G = 50\,000\, n\, T\,(T - T_0) \qquad (32a)$$

For 6197,

$$G = 100\,000\, n\, T\,(T - T_0) \qquad (32b)$$

For pumice,

$$G = 210\,000\, n\, T\,(T - T_0) \qquad (32c)$$

Since the numerical coefficient in Equations (32) must be the function, ψ, it can be written that

$$G = \frac{K\,n}{T_0^2}\, T\,(T - T_0) \qquad (33)$$

in which T_0 is defined by Equation (20) and K is a constant.

PUBLISHED AUTHORITIES

The following representative formulas given by other authorities are briefly reviewed herein as comparisons:

I.—A Schoklitsch.—Using additional experimental data of his own, but mainly the classic flume measurements by Gilbert, Schoklitsch developed the following formula[18] for uniform quartz grains of approximately the same density:

$$G = \frac{436.5}{\sqrt{D}}\, S^{1.5}\, B\,(q - q_0) \qquad (34)$$

in which G is the bed-load movement in pounds per second, D is the grain diameter, in millimeters, and q_0 is the critical discharge to move sand per unit width of channel, in cubic feet per second. The value of the latter is

$$q_0 = 0.00021\, \frac{D}{S^{4/3}}$$

II.—M. Fabre.—The results[19] obtained by the laboratory at Zurich, Switzerland, on gravels ranging between charcoal, the density of which approximates that of water, and baryta (protoxide of barium), of specific gravity greater than 4.0, lead to the following general relationship:

$$G = 2.16\, \frac{S^{1.5}\, Q}{\rho_e^{1/3}} - 20.70\, D\, \rho_e^{7/9} \qquad (35)$$

The equivalent critical discharge is $Q_0 = k\, \frac{\rho_e^{7/9}\, D}{S^{3/2}}$

---

[18] "The Schoklitsch Bed Load Formula," by S. Shulits, Assoc. N. Am. Soc. C. E., *Engineering*, June, 1936.

[19] "Mesure des debits solides des cours d'eau," par M. Fabre, *Annales des Ponts et Chaussées*, Vol. 8, 1934.

III.—Meyer-Peter.—In studying the results obtained with gravels of the same density but of different diameters, and with different slopes, the Swiss engineers[20] have arrived at a relationship of the form:

$$G = (a\,S\,Q^{2/3} - b\,D)^{3/2} \qquad \text{(36)}$$

and the equivalent critical discharge is

$$Q_0 = k\left(\frac{D}{S}\right)^{3/2}$$

in which a, b, and k are constants.

IV.—G. K. Gilbert.—The final expression by Gilbert[17] for bed-load movement, in which the slope, discharge, and fineness (reciprocal of D) are considered as of primary importance, is

$$G = k\,F\,(S - S_0)^{0.93 \text{ to } 2.37}\,(Q - Q_0)^{0.81 \text{ to } 1.24}\left(\frac{1}{D} - \frac{1}{D_0}\right)^{0.50 \text{ to } 0.62} \qquad \text{(37)}$$

or, approximately,

$$G = \frac{a}{D^{0.58}}\,S^{1.59}\,Q^{1.02} - b \qquad \text{(38)}$$

in which F is a shape factor, which is constant for a given ratio of depth to width of channel, and k, a, and b are constants. Those notations with the subscript, 0, are values for competent conditions to cause transportation.

V.—United States Waterways Experiment Station.—Data on the rate of sand movement obtained from experiments at the U. S. Waterways Experiment Station[10] conformed to the following relationship (after the formation of riffles):

$$G = \frac{k}{n}\,(T - T_0)^{1.5 \text{ to } 1.8} \qquad \text{(39)}$$

The contradiction of Equation (39) with that of the writer seems that of the reciprocal arrangement of Manning's n. In *Paper No. 17*, of the Experiment Station,[10] it has been concluded that "in general, the finer the sand mixture, the larger was the riffle size, and, consequently, the higher the value of n". Now, from all formulas given herein, G is always inversely proportional to a certain function of D; therefore, the sand movement is greater for finer material. If the finer material is more favorable for higher riffle development, then the sand movement must vary directly instead of inversely with Manning's n if a first power is used.

Exner's[21] expression for dune (riffle) velocity is

$$v_r = \frac{k}{(d - \xi)^2} \qquad \text{(40)}$$

in which ξ is the height of the surface of the dune, in feet. This, again, indicates that the larger the dune, the faster it will travel.

[21] "Uber die Wechselwirkung zwischen Wasser und Geschiebe in Flussen," von F. M. Exner, Wien, Aka. Sci. Ber., Vol. 134, 1935.

VI.—C. H. MacDougall.—The form of equation that has been found to fit the data accumulated at the Massachusetts Institute of Technology[22] is

$$G = a\, S^b\, (Q - Q_0) \qquad (41)$$

The constants, a and b, are interrelated, and also dependent upon D and M. They range from 100 to 1 000 and from 1.25 to 2.00, respectively.

VII.—H. Nakayama.—With certain restricted conditions, possible variations of bottom slopes, discharges, modes of flow, etc., were experimented with, and the results[23] obtained yielded the relation:

$$G = (\alpha + \beta\, S)\, Q\, (V^2 - V_0^2)$$

in which α is found to be small compared with $\beta\, S$. Further, assuming that V_0^2 is small compared with V^2, and may be neglected,

$$G = \beta\, S\, B\, d \left[\frac{1.486}{n} \right]^3 (S\, d)^{3/2} = \frac{K}{n^3}\, T^{2.5}$$

Manning's n may be taken as proportional to $D^{1/6}$ or $\xi^{1/6}$, so that, $G = \frac{K}{\sqrt{D}}\, T\, (T - T_0)$, or,

$$G = \frac{K}{\sqrt{\xi}}\, T\, (T - T_0) \qquad (42)$$

VIII.—S. D. Chyn.—From experiments made at the Massachusetts Institute of Technology on sands bigger than No. 48 mesh ($d > 0.5$ mm), S. D. Chyn[24] has obtained the following formula:

$$G = \psi\, V^p\, (T - T_0) \qquad (43)$$

in which ψ is a function of the sand. The exponent, p, being a function of Manning's n, has three distinct values for any one material, corresponding, respectively, to a smooth bed, to a bed being dragged, and to a riffled bed. That is, before riffles have developed, p is a function of the diameter of the sand grains; after their formation, it is a function of the size of the riffles.

IX.—F. Schaffernak.—Materials used in Schaffernak's[25] tests were obtained from the Danube River; experiments were performed both on samples of uniform size and on definite mixtures. The tests indicated that after the critical bottom velocity is exceeded, the capacity of transporting sand is directly proportional to the square of the bottom velocity. In connection with the possible application to conditions in natural streams, it is concluded that "for granular materials smaller than 5 mm, in a natural stream with surface slopes remaining approximately constant, du Boys' formula is applicable for determining the capacity of the stream."

ESTIMATE OF BED-LOAD MOVEMENT IN A RIVER SECTION

The general formula (Equation (20)) derived previously can be applied to a natural stream for a rough estimate[26] of the rate of its transportation. Further, it has been shown that the critical tractive force is constant for a certain material, and that it may be expressed as

$$T_0 = 0.0175 \left[\frac{\sigma - \rho}{\rho} D\, o^{1/3} \right]^{\beta} = w\, S\, d_0$$

If the slope of the stream and the value of T_0 for its bed material are known, d_0 can be computed. In Fig. 12 (*a*), it is evident that motion and hence transportation of bed material will take place only at and below the depth, d_0—that is, on the surface, $C\,E\,D$—and that there is no motion on the sides, $O\,C$ and $D\,F$. Actual observations by Kurzmann[27] support this theoretical consideration. The area, $A\,C\,E\,D\,B$, is thus called the effective area. Using the general formula and taking O as origin,

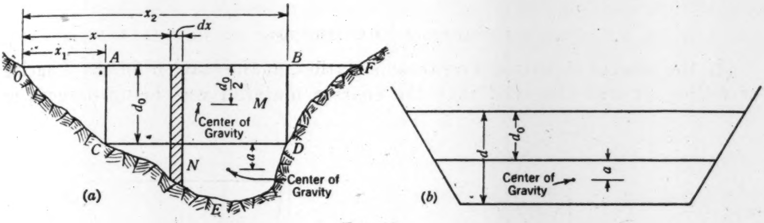

FIG. 12

$$G = \psi \int_{x_1}^{x_2} n\, T\, (T - T_0)\, dx = \psi \int_{x_1}^{x_2} n\, w^2\, S^2\, d(d - d_0)\, dx$$

$$= k \left[\int_{x_1}^{x_2} d^2\, dx - d_0 \int_{x_1}^{x_2} d\, dx \right]$$

The first integral is an expression of the moment of area about the surface. Dividing the total effective area into a rectangle, $A\,B\,C\,D$, called M, and an area, $C\,E\,D$, called N, the center of gravity of which is calculated and located at a distance $(d_0 + a)$ below the water surface,

$$2 \int_{x_1}^{x_2} (d\, dx)\, \frac{d}{2} = 2 \left[\frac{M\, d_0}{2} + N\, (d_0 + a) \right] = M\, d_0 + 2\, N\, (d_0 + a)$$

The second integral is simply an area $(M + N)$, and,

$$d_0 \int_{x_1}^{x_2} d\, dx = d_0\, (M + N)$$

Combining,

$$G = k\, [M\, d_0 + 2\, N\, (d_0 + a) - (M + N)\, d_0] = k\, N\, (d_0 + 2\, a) \ldots (44)$$

[27] See "Wasserbauliche Strömungslehre," by P. Némenyi, 1933, p. 139.

from which it is seen that the quantity of sand moved is proportional to the area below the critical depth, d_0, times approximately the mean depth of the total effective area.

The application to a trapezoidal section (Fig. 12 (*b*)) is still simpler. Let A be the total effective area of the section; A_0, the upper trapezoid; and N, the lower trapezoid below the depth, d_0. Since a is approximately equal to $\frac{(d - d_0)}{2}$, then

$$G = \psi\, n\, w^2 S^2 N\,(d_0 + 2\,a) = \psi\, n\, w^2 S^2 d(A - A_0) = k\, d^{0.5} S^{1.5}\,(Q - Q_0) \quad (45)$$

which approximates the general form of Equations (32).

SORTING PHENOMENON

In the present experiment on transportation, at the stage of initial dragging or rolling, it was observed that the coarser material was being dragged or rolled more rapidly than the finer. L. G. Straub,[28] Assoc. M. Am. Soc. C. E., noticed the same phenomenon in his experiments on flume traction. He observed that a surprisingly uniform gradation took place from one end of the flume to the other, despite the fact that the original material was of quite uniform size particles.

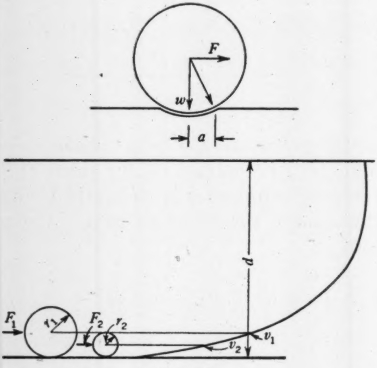

FIG. 13

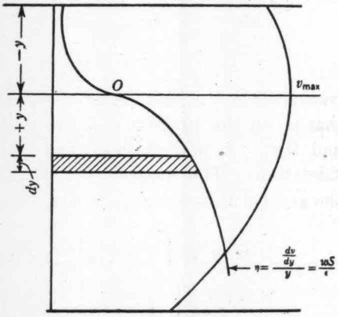

FIG. 14

The cause of this sorting is illustrated in Fig. 13, which shows two particles of different sizes on the bottom of the flume. The velocity distribution curve is horizontally exaggerated. Consider, first, the particles sliding on the surface. In turbulent flow the pressure on the particle is proportional to the velocity squared. By equating the pressure of the bottom velocity head on a spherical particle to the frictional resistance of the bed at impending motion,

$$\pi\, r^2\, w\, \frac{V_b^2}{2\,g} = f\, \frac{4}{3}\, \pi\, r^3\, (\gamma - w)$$

---

[28] "Some Observations of Sorting of River Sediments," by L. G. Straub, *Transactions*, Am. Geophysical Union, 1933.

and

$$V_b = \left[\frac{4}{3} f\, 2\, g \frac{\sigma - \rho}{\rho} r\right]^{1/2} \propto \sqrt{r} \ldots\ldots\ldots\ldots\ldots (46)$$

If the velocity distribution curve is of parabolic form, $v = k\, r\, (2\, d - r)$, and if, in addition, r is small compared with $2\, d$, $v \propto r$. If $r_1 = 2\, r_2$, the larger sphere will be moved by a velocity only 1.414 times as great as that required to move the smaller one. Actually, the velocity, v_1, at a distance, r_1, from the bed, is likely to be more nearly $2\, v_2$, for the velocity increases almost linearly near the bottom. Hence, the coarser particle is more easily and quickly moved than the finer one.

Next, consider particles rolling along. Equating the moment of the frictional resistance of the bed to that of the water pressure on a particle

$$\pi\, r^3\, w \frac{V_b^2}{2g} = \frac{4}{3} \pi\, r^3\, (\gamma - w)\, a$$

in which a, as shown in Fig. 13, is called the coefficient of rolling resistance and may be assumed, in the case of a soft bed, to be proportional to the radius of the particle, that is, $a = F\, r$. In this case, V_b is again expressed by Equation (46). Therefore, the sorting phenomenon is independent of the mode of movement; it exists either in sliding or in rolling.

In experiments on transportation of a graded sand, it is usually found that a large percentage of the coarser constituents is sorted out and transported. That this should occur can be demonstrated from the general equation,

$$G = \frac{k}{(D)^{2\beta}} T\, (T - T_0)$$

in which β varies from $\frac{1}{2}$ to 1 according to Equation (20). If the change in T_0 due to the change of D is negligible in comparison with T, then, approximately,

$$G = K \left[\frac{a}{(D_a)^{2\beta}} + \frac{b}{(D_b)^{2\beta}} + \frac{c}{(D_c)^{2\beta}} + \cdots \right] = K\, \Sigma \frac{p}{(D)^{2\beta}} \ldots\ldots (47)$$

in which a, b, c, $\cdots$, and p are the percentages by weight of the material transported. To have G a maximum, differentiate with respect to D, taking both G and p as variables, and equate to zero:

$$DG = K \left[- \frac{2\, \beta\, p}{D^{1+2\beta}} dD + \frac{1}{D^{2\beta}} dp \right] = 0$$

$$\frac{dp}{p} = 2\, \beta \frac{dD}{D}$$

or

$$\frac{p_1}{p_2} = 2\, \beta \left(\frac{D_1}{D_2} - 1 \right) + 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

Equation (48) is the general formula for sorting in sand transportation. Note, for example, that if the coarser particles are twice the diameter of the finer ones (that is, if $D_1 = 2\, D_2$ and $\beta = \frac{1}{2}$ for fine sands), then $\frac{p_1}{p_2} = 2$. In other words, two-thirds of the material transported will consist of coarse particles and one-third of fine particles.

SUMMARY: PART II

(1) An equation of the du Boys type is found to fit best the present experimental data. The specific form suggested is $G = \frac{K\,n}{T_0^2} T\,(T - T_0)$.

(2) The advance of riffles is proportional to the fifth power of the mean velocity of the flow.

(3) Sorting always takes place in graded sands, irrespective of the mode of motion of the particles, the coarser particles moving in greater quantities than the finer.

PART III.—TRANSPORTATION OF MATERIAL IN SUSPENSION

METHOD OF EXPERIMENT

Suspension was visible in the flume as soon as saltation began. When saltation was strong and accompanied by dune formation of the bed material, bands of particles were lifted vigorously and dispersed into suspension. The present observations were usually made under the latter conditions, and with the bed continuously changing, and are, therefore, only approximate. However, the results were consistent enough to illustrate the principles reviewed and developed in this part of the paper.

In addition to the data required in the study of transportation by traction, it was necessary in the present case to measure the velocity distribution of the section and to obtain samples of the suspended load. Pitot tube readings were taken at vertical intervals of about 1 in. in the axial plane of the flume. At the same time samples were taken at prescribed depths by means of a glass tube, $\frac{1}{4}$ in. in diameter, equipped with a suction bulb. These samples were transferred to a flask, in which the suspended particles soon settled to the bottom, and the concentration, in particles per cubic centimeter, was obtained by direct count of the particles and measurement of the volume of water. No attempt was made to investigate the size of suspended particles microscopically.

During these tests, feeding at the up-stream end was stopped to ensure that all the suspended load was supplied from the bed itself.

LIFTING FORCE NEAR BOTTOM

The lifting force on a particle resting on the bed may be considered as due mainly to the pressure of a velocity head. The particle will tend to lift when this vertical force just balances its effective weight in water. If V_l is the velocity of flow near the bottom required to produce this lift, the balance can be expressed mathematically by,

$$w \frac{V_l^2}{2g} \frac{\pi D^2}{4} = \frac{\pi D^3}{6} (\gamma - w)$$

whence

$$V_l^2 = \frac{4}{3} g \frac{\sigma - \rho}{\rho} D \ldots\ldots\ldots\ldots\ldots\ldots (49)$$

Comparing Equation (49) with Equation (46),

$$\frac{V_l}{V_b} = \frac{1}{\sqrt{f}} \ldots\ldots (50)$$

in which f is the coefficient of friction between particles in water. The present experiments yield an average ratio of 1.4; this will correspond to $f = 0.51$. The value of f usually varies with ρ_e and D.

Gilbert observed in his studies of flume transportation that vortex rings with transverse axes occur near the bottom of the flume. Thus, the phenomenon of lifting can also be interpreted in a mathematical way[29] by "circulation." Since the radius of the vortex ring is so large compared with the size of the grain, the vortex ring may be considered as an imaginary large hollow cylinder. By the interrelated action of the horizontal velocity and the circulation, two equal forces are created to support the particle; one is due to the change of momentum and the other to the difference of velocity head above and below the particle. The final form of total lift is $\rho\ V\ \Gamma$, in which ρ and V are the density of the liquid and the velocity of flow, and Γ is the circulation, which is shown in aeromechanics, to be proportional to V. This agrees with the previous result that the lifting force is proportional to the square of the velocity.

DISTRIBUTION OF SUSPENDED SEDIMENT

The general equation[30] for distribution of suspended sediment is,

$$c = c_0\, e^{\omega \rho \int_0^y \frac{dy}{\epsilon}} \ldots\ldots (51)$$

in which ϵ, defined by $-\dfrac{w\ S\ y}{\dfrac{dv}{dy}}$, is the Austausch coefficient; ω is the settling velocity of the solid particles; c is the sediment concentration at the elevation, y, and c_0 is the sediment concentration at the elevation of maximum velocity. If ϵ is a constant, Equation (51) can be expressed as

$$c = c_0\, e^{\omega \rho y / \epsilon} = c_0\, e^{\alpha y} \ldots\ldots (52)$$

y being measured downward from the surface. The equation developed by Hurst[31] from experiments with sand stirred up into suspension by propelling the water in a cylinder, is of a similar form. He considers that in any layer, dy, the weight of the particles will balance the pressures due to the impact of particles from above and below. The result is:

$$c = c_0\, e^{\beta y} \ldots\ldots (53)$$

in which $\beta y = \dfrac{3\, g}{\bar{u}^2} \dfrac{\sigma - \rho}{\rho} \displaystyle\int_0^y dy$, and $\bar{u}$ is the absolute mean velocity of the particles. Equations (52) and (53) show agreement in that both α and β

[30] "Distribution of Silt in Open Channels," by J. E. Christiansen, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, 1935.

[31] "The Suspension of Sand in Water," by H. E. Hurst, *Proceedings*, Royal Soc., London, Vol. 124 1929.

depend on the size and specific gravity of the grains and the turbulence of the flow. In the closing discussion on his paper entitled "Modern Conceptions of the Mechanics of Fluid Turbulence", Hunter Rouse,[32] Assoc. M. Am. Soc. C. E., has constructed a set of theoretical sediment distribution curves based on the assumption that the universal logarithmic velocity curve actually extends to the free surface of a wide stream. The general equation governing the sediment distribution is,

$$\frac{c}{c_a} = \left[\frac{y\,a}{(d-y)\,(d-a)}\right]^z \quad \text{.....................} (54)$$

in which $z = \dfrac{\omega}{k\,V\sqrt{\dfrac{f}{8}}}$. The equation is applicable down to some arbitrary depth $(d - a)$, beyond which the suspension becomes mixed with the tractive load. In the parameter, z, k is an universal constant having an empirical value 0.4 and f is the roughness coefficient of the channel.

Thus, a general conclusion can be drawn that whether the velocity distribution is parabolic or logarithmic, the vertical distribution of suspended sediment in turbulent streams is exponential.

Experimental Verification

Tests have been made on sediment distribution as described; the results plotted do not agree with the theoretical Equation (51), because this equation is presumably derived for a considerably wide channel suffering no side restriction. Assuming ϵ to be a constant (as it is for a parabolic velocity distribution), and S, the energy gradient, to be practically constant at any depth, y, then Equation (51) can be written in the form,

$$c = c_0\,e^{k w S y} = c_0\,e^{\phi T}$$

which means that the sediment distribution is an exponential function of the tractive force at the depth. This is particularly in agreement with Bottomley's idea[33] that the silt transportation force depends mainly on the frictional resistance of the bed, or, in other words, the tractive force on the bed. The flume used in the present experiments is very narrow and it is evident that the depth, d, cannot take the place of the hydraulic radius, R, and, therefore, the exponent, $\omega\,\rho \displaystyle\int_0^y \frac{dy}{\epsilon}$, must be adjusted accordingly. Using Equation (12), assuming an average value for d of $\frac{1}{2}$ ft, and taking $n_b = 2\,n_l$, the average tractive force becomes

$$\overline{T} = w\,S\,d\,\frac{1}{1 + \dfrac{2\,d}{B}\,\dfrac{n_l}{n_b}} = \frac{1}{2}\,T$$

Even this equation, however, will not apply exactly in the present case, because both the depth and the channel roughness vary continuously; hence, the exact correction is unknown. Several trials of plotting have shown, however, that the exponent, $\frac{\omega \, \rho}{2} \int \frac{dy}{\epsilon}$, fits the experimental data better than any other.

---

[32] *Proceedings*, Am. Soc. C. E., January, 1937, p. 116.

[33] "A New Theory of Silt and Scour," by W. T. Bottomley, *Engineering*.

Before proceeding further, it is necessary to compute the settling velocity of sand in water. Rubey's formula,[34] reduced to a temperature of 15° C, is

$$\omega = \frac{7}{D} \left[\sqrt{134.5 \, (\sigma - 1) \, D^3 + 1} - 1 \right]$$

D being expressed in millimeters and ω in millimeters per second. The values of ω for pumice, Sand No. 6197, and emery are, respectively, 0.0886, 0.0853, and 0.1137 ft per sec.

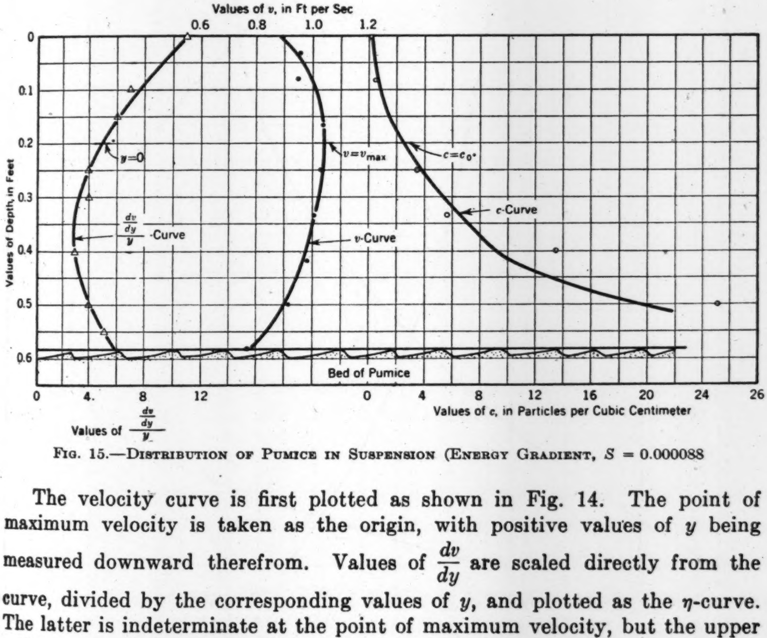

FIG. 15.—DISTRIBUTION OF PUMICE IN SUSPENSION (ENERGY GRADIENT, $S = 0.000088$

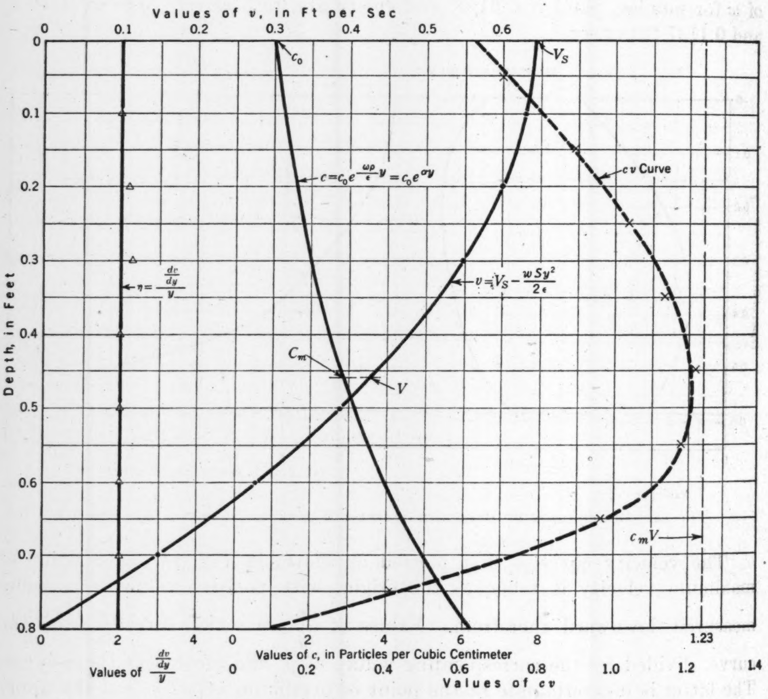
The velocity curve is first plotted as shown in Fig. 14. The point of maximum velocity is taken as the origin, with positive values of y being measured downward therefrom. Values of $\frac{dv}{dy}$ are scaled directly from the curve, divided by the corresponding values of y, and plotted as the η-curve. The latter is indeterminate at the point of maximum velocity, but the upper and lower branches can be joined by a smooth continuous curve. The area of the η-curve to any co-ordinate, y, is equal to, $w \, s \int_0^y \frac{dy}{\epsilon}$, and can be measured by planimeter, the values always being taken as positive. From these graphical data, silt distribution curves can be computed once the specific concentration, c_0, and the value of ω are known. Curves for the various bed materials tested (see Fig. 15 for a typical example) were prepared on that basis. The velocity distribution curve was first plotted and the η-curve computed. Then, the observed concentrations were plotted and joined with a tentative curve, and the abscissa for $y = 0$ was taken as c_0. Theoretical values of c for other depths were then computed and plotted. If this curve did not agree with the original trial curve, the latter was modified accordingly—that is, varied to give a new value for c_0—and the computations were repeated.

---

[34] "Settling Velocities of Gravel, Sand, and Silt Particles," by W. W. Rubey, *American Journal o Science*, Vol. 25, 1933.

TOTAL LOAD IN SUSPENSION

The following theoretical study assumes a parabolic velocity distribution, with maximum velocity at the surface (Fig. 16), and the silt concentration at



. 16.—SILT DISTRIBUTION AND TOTAL SUSPENDED LOAD IN STREAM WITH PARABOLIC VELOCITY DISTRIBUTION

the surface is taken as c_0. Then the mean value of the silt concentration throughout the depth is

$$c_m = \frac{1}{d}\int_0^d c\,dy = \frac{c_0}{d}\int_0^d e^{\alpha y}\,dy = \frac{c_0}{d}\left[\frac{e^{\alpha y}}{\alpha}\right]_0^d = \frac{c_0}{\alpha\,d}(e^{\alpha d} - 1)\ldots\ldots(55)$$

in which $\alpha = \frac{\omega\,\rho}{\epsilon}$. For the case plotted in Fig. 16, the following values have been assumed: $V_S = 0.64$, $d = 0.80$, $S = 0.00155$, $\omega = 0.0575$, and $c_0 = 1$; these are more or less the average conditions of the experiment

$$\omega\,\rho\int_0^v \frac{dy}{\epsilon} = \omega\,\rho\int_0^v \frac{\frac{dv}{dy}}{w\,S\,y}\,dy = \frac{\omega}{g\,S}\int_0^v \frac{\frac{dv}{dy}}{y}\,dy = \frac{\omega}{g\,S}\,\eta\,y = \alpha\,y$$

For a parabolic velocity distribution curve, η is a constant, its value in the present case being 2. Therefore, $\alpha = \frac{0.0575 \times 2}{32.2 \times 0.00155} = 2.303$; $\alpha\,d = 1.843$; and, substituting in Equation (55), $c_m = 2.88$ particles per cubic centimeter. Equating c_m to c to locate the depth of the point of mean concentration, $e^{\alpha y} = 2.88$; whence, $y = 0.46 = 0.575\,d$ from the surface.

Assuming that the vertical co-ordinates of the mean velocity and the mean concentration are nearly the same, the total suspended load, P, may be expressed approximately by,

$$P = c_m\,q = c_m\,V\,d = \frac{2}{3}\frac{c_0}{\alpha}\left(e^{\alpha D} - 1\right) V_S \ldots\ldots\ldots\ldots\ldots (56)$$

in which c_0 is in pounds per cubic foot. Substituting the numerical values for an illustration, $P = 0.985$ (pound per second per foot of width).

If the velocity distribution is parabolic but the bottom velocity is not equal to zero, the following approximation may be used:

$$V = \frac{1}{d}\int_0^d v\,dy = \frac{1}{d}\int_0^d \left[V_S - \frac{w\,S\,y^2}{2\,\epsilon}\right] dy = \left[V_S - \frac{\eta\,d^2}{6}\right]$$

and

$$P = \frac{c_0}{\alpha}\left[e^{\alpha d} - 1\right]\left[V_S - \frac{\eta\,d^2}{6}\right] \ldots\ldots\ldots\ldots\ldots\ldots (57)$$

Equations (56) and (57) do not give the exact total suspended load even when the co-ordinates of the mean velocity and the mean concentration are at the same elevation; the resulting value is always somewhat too high. However, the following exact solution may be applied to any cases as long as the velocity distribution is parabolic and the silt distribution exponential:

$$P = \int_0^d c_0\,v\,dy = c_0\int_0^d e^{\alpha y}\left[V_S - \frac{\eta\,y^2}{2}\right] dy$$

$$= \frac{c_0\,V_S}{\alpha}\left[e^{\alpha d} - 1\right] - \frac{c_0\,\eta}{2\,\alpha^3}\left[(\alpha\,d)^2\,e^{\alpha d} - 2\,(\alpha\,d - 1)\,e^{\alpha d} - 2\right] \ldots (58)$$

This is the general equation for total load in suspension. c_0 is the concentration at $y = 0$; that is, at the surface where the velocity is a maximum. If $v = 0$ at the depth, d, $\frac{\eta}{2} = \frac{V_S}{d^2}$; therefore,

$$P = \frac{c_0\,V_S}{\alpha^3\,d^2}\left[2\,e^{\alpha d}\,(\alpha\,d - 1) - (\alpha\,d)^2 + 2\right] \ldots\ldots\ldots\ldots (59)$$

Substituting the numerical values, $P = 0.755$ (pound per second per foot of width). Curves of v, η, and c are plotted in Fig. 16. The ordinates of V

and c_m happen in this case to be at the same elevation. Their product gives the vertical line, $c_m V$; the area bounded by this line, the surface, and the axes, gives the total load of suspension by Equation (56). More accurately the product of c and v at various elevations should be plotted to obtain the curve, $c v$, the area to the left of which is the total load of suspension by Equation (59).

Straub[15] suggested the following (Equation (60)) derived from typical velocity-depth curves and typical suspended sediment-concentration curves, to determine the total quantity of silt transported in suspension per second:

$$P = \left[\tfrac{5}{8}\, c_{0.2d} + \tfrac{3}{8}\, c_{0.8d}\right] q \qquad (60)$$

In the present theoretical case, $c_{0.2d} = 1.5$, and $c_{0.8d} = 4.3$, so that $P = 0.855$ (pound per second per foot of width) which is 13.2% greater than the value by the exact solution, and 13.2% less than the value by the approximate solution. For practical purposes Straub's empirical formula is probably of the right order. For a rough estimate of the quantity of silt transported by a river it is highly recommended, because it is fairly simple to make two soundings at the proper depths, to collect the silt concentration samples. However, for a theoretical parabolic distribution of velocity, Equation (58) is convenient and more accurate. Of course for a refined determination, an arithmetic integration of the product of V and c at numerous elevations is needed.

EFFECT OF SILT TRANSPORTATION ON VELOCITY AND STREAM ENERGY

Transportation by traction affects the mean velocity of the stream by changing the roughness of the bed and, consequently, by varying the rate of dissipation of stream energy. Transportation by suspension, if not of appreciable quantity, will not affect the mean velocity very much. In rivers such as the Yellow River, however, with a maximum silt content of approximately 10% by weight during flood flows, and the Wei and Fen Rivers, tributaries of the Yellow River, with maximum silt contents as high as 46% and 20%, the suspended load will affect the mean velocity much more seriously than the bed load.

Evidently, the silt load in suspension will affect the mean velocity mainly in two respects: First, by changing the energy content of the stream; and, second, by changing the density and viscosity of the fluid. Changes in kinetic energy along the course of a stream due to the addition of silt are relatively small; further, little energy is consumed in supporting the débris. Therefore, it may be assumed that the change of kinetic energy due to the addition of silt is nil. Let $k\, w\, V\, Q$ be the kinetic energy of a clear stream. If V_1 is the mean velocity of the same stream with a quantity, $\alpha\, Q_1$, of silt in suspension, then the kinetic energy is represented by $k\,[w\, Q_1 + \alpha\, Q_1\, (\gamma - w)]\, V_1$. Equating the two expressions by assuming that the cross-sectional area remains the same, and solving for V_1:

$$V_1 = \sqrt{\frac{w}{w + \alpha\,(\gamma - w)}}\; V = \frac{V}{\sqrt{1 + \alpha\left(\dfrac{\sigma}{\rho} - 1\right)}} \qquad (61)$$

Taking $\sigma = 2.65$, $\rho = 1$, and $\alpha = 10\%$ (for the Yellow and Colorado Rivers), $V_1 = \frac{V}{1.079}\cdot$ The velocity of flow is thus retarded by 7.4 per cent. For the Wei River with $\alpha = 46\%$, $V_1 = \frac{V}{1.326}$; that is, the velocity is decreased by 24.5 per cent.

This diminution of velocity of flow by silt content may serve to explain the "saturation" stage of stream capacity in supporting débris, for it is clear that silt will be transported in suspension only as long as the stream velocity exceeds the competent velocity to cause lifting up of particles.

Gilbert's observations[17] showed the same result. He concluded that under all conditions, streams are retarded by their suspended loads. The average of the thirteen velocities found for the loaded streams was 10% less than the corresponding average for unloaded streams.

In a paper published by Rubey[35] further light is thrown on this subject. By assuming that the change of kinetic energy is negligible, and equating the loss of potential energy of the flow (water + load) to the energy consumed in friction plus that consumed in transporting the load, he derived the following expression:

$$(W + L)\, g\, S\, V = \kappa\, \rho_f\, p\, V^4 + L\frac{\sigma - \rho}{\sigma} g\, \omega \ldots\ldots\ldots\ldots (62)$$

in which ρ_f is the density of flow (water + load); W and L are the weights of water and load, passing the section each second, respectively; κ, the skin friction coefficient of the channel; and p the wetted perimeter. When $L = 0$, $W\, g\, S\, V = \rho_f\, Q\, g\, S\, V = \rho_f\, A\, g\, S\, V^2 = \kappa\, \rho_f\, p\, V^4$; and $V = \left[\frac{g}{\kappa} R\, S\right]^{1/2}$, which is the familiar Chezy equation with its coefficient, C, expressed as $\left(\frac{g}{\kappa}\right)^{1/2}\cdot$ Substituting $C^2\, R\, S$ for V^2 in Equation (62),

$$\frac{\frac{L}{W}\frac{\sigma - \rho}{\sigma}\omega}{\left(1 + \frac{L}{W}\right) S\, V} = 1 - \frac{\kappa}{g} C^2 = \delta \ldots\ldots\ldots\ldots\ldots\ldots (63)$$

When $L = 0$, $C = \sqrt{\frac{g}{\kappa}}\cdot$ When there is suspended load, C will be less than $\sqrt{\frac{g}{\kappa}}$. In the twenty-two experiments of Gilbert on débris-laden streams recalculated by Rubey, the values of $\left(1 - \frac{\kappa\, C^2}{g}\right)$ range from 0.007 to 0.070, with a median value of 0.025; that is, under the conditions of these experiments, an average of 97.5% of the total stream energy appears to have been lost in friction, and only 2.5% in transporting débris. In this equation $\frac{L}{W}$ is the fractional weight of the load in the stream. In the case of the Yellow River flood in 1931, with

---

[35] "Equilibrium Conditions in Débris-Laden Streams," by W. W. Rubey, *Transactions*, Am. Geophysical Union, 1933.

39% loess suspension, δ was 0.0613 (taking $\sigma = 2.63$; $\omega = 0.004$ ft per sec, $S = 0.000135$, and $V = 84$ ft per sec).

Another substitution of the Chezy formula into Equation (63) gives,

$$\frac{\dfrac{\sigma - \rho}{\sigma}}{C\left(1 - \dfrac{\kappa}{g} C^2\right)} \times \frac{L\,\omega}{\rho_f\,Q} = S^{3/2}\,R^{1/2} \ldots\ldots\ldots\ldots\ldots (64)$$

Equation (64) states the general relationships that the graded slope varies directly as the quantity of débris that must be carried, directly as the average size of the material, and inversely as the discharge of the stream.

Let $X = \dfrac{\text{mean depth}}{\text{mean width}}$. Then $R = \dfrac{A}{p} = \dfrac{Q}{C\,\sqrt{R\,S}\,p} = \dfrac{Q\,X}{C\,R^{3/2}\,S^{1/2}}$, and $R^{1/2} = \left[\dfrac{Q\,X}{C\,S^{1/2}}\right]^{1/5}$. Substituting this in Equation (64),

$$S^{7/5}\,X^{1/5} = \frac{\dfrac{\sigma - \rho}{\sigma}}{C^{4/5}\left(1 - \dfrac{\kappa}{g} C^2\right)\rho_f} \times \frac{L\,\omega}{Q^{6/5}} \ldots\ldots\ldots\ldots\ldots (65)$$

In this expression the settling velocity,[34] ω, is proportional to $D^{1/2}$ for sand particles coarser than 1.55 mm in diameter, and to D^2 for sand particles finer than 0.145 mm in diameter. Consequently, the equation can be written in the form, $L \propto \dfrac{S^{\alpha}\,Q^{\beta}\,X^{\gamma}}{D^{\phi}}$.

Table 6 lists values of these exponents as obtained from several sources:

§ By assuming that all tractive transportation is lifted in suspension, that is, $L = G$.

SUMMARY: PART III

(1) Theoretically, the force required to lift a particle from the bottom of a stream is about 40% greater than that required to move it along the bed.

(2) The general equation for vertical distribution of silt in two-dimensional flow is of the form of Equation (51).

(3) The mean silt concentration throughout a depth, d, may be computed by Equation (55), in which $\alpha = \dfrac{\omega\,\rho}{\epsilon}$.

(4) The total suspended load in a stream may be well estimated by the empirical formula, Equation (60). Equation (58) is an exact equation, assuming a parabolic distribution of velocities.

(5) Silt transportation tends to decrease the mean velocity of flow. However, the energy consumed in supporting the load is only a small fraction of the total energy of the stream, which is mainly dissipated in overcoming the frictional resistance of the channel.

ACKNOWLEDGMENTS

The writer is indebted to Professor A. H. Gibson for his advice and interest in the problem, and for offering every possible facility in the use of the Whitworth Engineering Laboratory of Victoria University, at Manchester, England. Mr. J. Allen helped to perform the experiment and corrected the original manuscript. Mr. S. D. Chyn, of Tsing Hua University, Peiping, China, read the paper and offered helpful criticism. The writer wishes also to express his sense of indebtedness to the Board of Trustees, Nanking, China, for the scholarship which enabled him to carry out the research.

APPENDIX

NOMENCLATURE

The following nomenclature is used throughout the paper:

A = area of cross-section, in square feet;
a = vertical distance from d_0 to center of gravity of N; also, an exponent;
B = surface width, in feet;
C = Chezy coefficient; also, a constant;
c = constant in tractive force equations; elsewhere, concentration of suspended sediment, in particles per cubic centimeter; or in pounds per cubic foot;
D = mean diameter of a sand particle, in millimeters;
d = depth in feet; d_0 = depth at which critical tractive force obtains;
e = base of natural logarithms;
f = coefficient of friction in water;
G = rate of sand movement, in pounds per second;
g = gravity acceleration, in feet per second per second;
i = slope of side of trapezoidal channel, horizontal over vertical;
k = a coefficient;
L = total weight of suspended load passing a given section in 1 sec;
M = Kramer's uniformity modulus (dimensionless); also, area of channel above d_0;
N = area of channel below d_0;
n = Manning's n; also number of layers of sand (in explanation of du Boys' formula);
o = ratio between longest and shortest diameter of a sand grain;
P = total suspended load, in particles per second per centimeter of width; or in pounds per second per foot of width;

p = wetted perimeter; also, percentage of material of a given size in a mixture of sand that has been transported by traction;

Q = discharge, in cubic feet per second;

q = discharge per unit width of channel;

R = hydraulic radius, in feet;

$\mathsf{R} = \frac{V\,d}{\nu}$ = Reynolds number (dimensionless);

r = radius of sand particle;

S = slope of water surface; S_0 = slope of bed;

T = unit tractive force, in pounds per square foot; $\overline{T}$ = average unit tractive force over entire wetted perimeter; T_0 = critical unit tractive force;

$\bar{u}$ = absolute mean velocity of suspended particles;

V, V_1 = mean velocity, in feet per second; V_s = surface velocity; V_b = bottom velocity; and V_l = lifting velocity;

v = velocity at any point, in feet per second; v_r = advance of riffles, in feet per second;

W = total weight of water passing a given section in 1 sec;

w = weight of water, in pounds per cubic foot;

X = ratio of mean depth of channel to mean width;

x = length measured along the bed;

y = vertical distance, variable;

z = ratio between length of sloping side and bottom width of trapezoidal channel;

α = angle between water surface and horizontal; also, coefficient in Schoklitsch equation; also, an exponent; in Part III, $\alpha = \frac{\omega\,\rho}{\epsilon}$;

α_0 = angle between bed and horizontal;

β = an exponent to the expression $[\rho_e\,D\,o^{1/3}]$;

γ = unit weight of sand; also, an exponent;

$\delta = \left[1 - \frac{\kappa}{g.} C^2\right]$, in Equation (63);

ϵ = Austausch coefficient $= -\frac{w\,S\,y}{\frac{dv}{dy}}$;

$\eta = \frac{\frac{dv}{dy}}{y}$;

κ = coefficient of skin friction (dimensionless);

μ = viscosity of fluid;

ν = kinematic viscosity of fluid;

ξ = height of riffle, in feet;

ρ = specific gravity of fluid; ρ_e, effective specific gravity of submerged sand particles; ρ_f, the specific gravity of flow (water + load);

σ = specific gravity of sand particles;

ω = settling velocity of sand particles in water, in feet per second.

DISCUSSION

HANS KRAMER,[36] M. AM. SOC. C. E. (by letter).—This paper, based on flume experimentation and correlation of data from the observations of previous investigators, adds another valuable chapter to the field of knowledge regarding the complex phenomena of sand movement. Because of its intimate relation with, and frequent reference to, the writer's previous work[37] in the same field, this discussion will be confined to Part I of Mr. Chang's paper, which treats the subject of "Flume Traction."

The author made use of a horizontal flume bed instead of one inclined to the same slope as the water surface because the necessity for the latter arrangement was considered doubtful. However, from a mathematical analysis of his observed data, Mr. Chang concludes "that the tractive force needed to move débris on a sloping bed parallel to the water surface is only one-half that needed on a horizontal bed." The hypothesis and conclusion appear irreconcilable. Professor Hubert Engels, the pioneer and dean among investigators in this special field, emphasized[38] the importance of uniform flow and the interrelation between bed slope and water-surface slope in experimentation of this nature. It is unfortunate, therefore, that Mr. Chang's observations have been beclouded unnecessarily by the introduction—or lack of elimination—of this important variable.

A similar comment is applicable to the uniformity modulus, *M*. The author states that the uniformity modulus of samples used in his experiments was not determined but, nevertheless, concludes—again by mathematical manipulation—"that the uniformity modulus, *M*, has practically nothing to do with the critical tractive force, and could be omitted." Inasmuch as Mr. Chang's experimentation purposely utilized only sands of uniform grain size ($M = 1$), whereas natural sand mixtures vary greatly in their gradation—and in *M*—it would appear that his extrapolated conclusion as to the effect of the uniformity modulus is beyond the limit of his own observations.

The painstaking determination of the mechanical properties of test samples, including microscopic measurements, deserves commendation. It is regrettable, however, that the determination of grain size by the standard method of sieve analysis was not included. It is believed that the grain size of sand used by other investigators, as listed in Column (6), Table 5, is based on the conventional sieve analysis curve. Inasmuch as standard sieving procedure results in larger apparent sizing than absolute physical measurement, Mr. Chang's size determinations are not directly comparable with those tabulated for other investigators.

It is also noted that Mr. Chang has adopted as a definition for "general movement" a set of conditions which are more comparable to the writer's definition for "medium movement" than to his definition of "general movement." A cursory review of the writer's observed data indicates that the magnitude of the critical tractive force based on his "general movement" is approximately 20% greater than that based on "medium movement." This variance in a basic definition, which forms a criterion for comparison of results, would appear to require the application of a corrective factor in the correlation of observations.

[38] "Versuche über den Reibungswiderstand zwischen strömenden Wasser und Bettsohle," by H. Engels, *Zeitschrift für Bauwesen*, 1912.

Mr. Chang's experimentation and treatise, while constituting another important step in the diagnosis of the complex phenomena of sand movement, may also be regarded as further proof of the difficulty of reconciling and correlating data observed and conclusions derived by different experimenters under widely divergent conditions. His attempt to simplify the problem by choosing to experiment with uni-granular sand, thereby eliminating the vexing variable of grain-size distribution, is a step in the right direction. However, it is believed that the ultimate, basic solution to this problem—both mathematical and physical—will not be clearly and convincingly obtained until the scientific viewpoint and procedure of the experimental physicist are adopted. The writer is convinced that further research to determine the independent variables which govern the very complex phenomena of sand movement by traction and the fundamental relation between these variables must seek simplification and idealization of the phenomena. To this end, it is suggested that future experimentation with artificial spherical or spheroidal grains—probably of glass—with colors, markings, etc., for statistical identification may develop the simple fundamentals of flume traction without the complicating influences of accidental and uncontrollable variations inherent in the use of natural sand specimens.

E. W. Lane,[39] **M. Am. Soc. C. E.** (by letter).—A very valuable contribution to the science of the transportation of solids by flowing water is presented in this paper. It seems to the writer that the reason for some of the lack of agreement of different experimenters on the values of critical tractive force for the movement of the various sizes of material is probably that initial movement is not a function of tractive force alone but of a combination of tractive force and turbulence. The traction is an average force over a considerable area, but the forces that move the first particles are probably intense local forces, acting only over a small area of the bottom, having a magnitude greater than the average force acting. The initial movement, therefore, would depend not only on the magnitude of the average force but also on the range above the average of the variable forces, due to the turbulence in the water. Therefore, initial movement would depend on both tractive force and turbulence. These two factors would also influence other degrees of movement, but it does not seem likely that turbulence would be of relatively as great importance in them as in the initial movement.

In his summary of Part 1, Item (5), the author concludes that the "resistance to motion of particles on a horizontal bed is nearly double their resistance on a sloping bed having the same inclination as the water surface." This would indicate that the motion of bed load is very sensitive to changes in the bed slope. The bottom of a stream where bed load is in motion is usually rough, with slopes both upward and downward in the direction of flow. Even in a laboratory flume there are sand waves such that the sand moves up slopes considerably steeper upward in the direction of flow than the water surface slopes downward in this direction. Sand waves were observed in the Mississippi by the late J. B. Johnson, M. Am. Soc. C. E.,[40] with an average height of 5 ft, and an average length of about 330 ft, indicating an upward slope of 1 in 66. The surface slope was probably only about one two-hundredths of this inclination. The depths of water ranged from 13 to 30 ft, with movement apparently throughout this range. It would be interesting to extend the analysis that led to the foregoing conclusion to see if it would indicate any motion at all up the slopes of the Mississippi sand waves. The effect of bottom slope on the bed load carried in a stream may be a factor that will make it very difficult to correlate field and laboratory results.

---

[39] Associate Director in Chg., Iowa Inst. of Hydr. Research, Univ. of Iowa, Iowa City, Iowa.

The author shows that a change in the law of bed-load transportation occurs at a grain size for quartz of about 0.5 mm, and states that this is best explained by turbulence. Since the law governing the settling rate of quartz grains changes at about the same size, may the change in the bed-load law not be related to the change of settling rate? There is good evidence that the law of transportation of material in suspension shows a similar sharp break at about this size.

The author concludes (see "Summary": Part III, Item (5)) that "silt transportation tends to decrease the mean velocity of flow." This conclusion is the opposite of that reached by A. B. Buckley, Jr.,[41] from observations in the Nile Valley. Surprisingly low roughness values have been obtained on some of the silt-laden rivers of North China by the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., and others, which support Mr. Buckley's conclusions. This is apparently a field which justifies much further research.

JOE W. JOHNSON,[42] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper the author has presented an excellent review of the problem of transportation by flume traction. He has also presented original data and conclusions that are welcome contributions to the knowledge of this phenomenon. Of particular interest to the writer is the section of the paper treating the formulas for rate of transportation. Therein is given a review of the published formulas and a new formula which is of the du Boys[14] type.

The writer reviewed a large number of formulas representing the data obtained from various experiments. Perhaps the most common type of formula is that of du Boys (Equation (26)), in which rate of movement is plotted against a function of tractive force. Also very common is the Schoklitsch-MacDougall type (Equation (41)), in which rate of movement is assumed to be proportional to excess power.[22] Authorities undertaking flume studies have usually presented their data in one of the common types of formulas, but, in many instances, with slight modifications. The result of such studies has been that there are approximately as many formulas describing the rate of sand movement as there are authorities on the subject. It was with this situation in mind that an investigation was made in 1937 to determine, for a certain set of published flume observations, whether a particular method of presenting data offered distinct advantages over other methods. In order to obtain an unbiased opinion in this determination, recourse was made to the methods of statistical analysis.

[42] Asst. Hydr. Engr., SCS, U. S. Dept. of Agriculture, Washington, D. C.

Flume-study observations published in United States Waterways Experiment Station *Paper No. 17* were used in the computations. These data are for U. S. Waterways Experiment Station Sand No. 1 which was tested in a concrete-lined flume, 2.416 ft wide and with slopes of 0.0010, 0.0015, and 0.0020. Only those data in which "general movement" occurred were used in this study. From the results of these measurements, computations were made to permit the data to be plotted according to the criteria of du Boys,[14] Chang, Meyer-Peter,[20] U. S. Waterways Experiment Station,[19] MacDougall,[22] and O'Brien.[43] It is noted that in Fig. 11 the author plots $\frac{G}{n_s}$ versus $T\ (T - T_0)$, whereas in the general statement of his formula (Equation (33)), $\frac{G}{n}$ is adopted as the dependent variable. In the discussion to follow, the parameters in Fig. 11 have been used. Figs. 17, 18, and 19 show the results of plotting the computed data according to various authorities. The curves were fitted by the method of least squares and their "goodness of fit" was tested by the χ^2-test. The equations for the various groups are, as follows:

The U. S. Waterways Experiment Station (Fig. 17):

$$G_1 = \frac{29\,400}{n}\,(d\,S - d_0\,S_0)^{1.41} \dots\dots\dots\dots\dots (66a)$$

Du Boys (Fig. 18(*a*)):

$$G_1 = 20\,860\,[T\,(T - T_0)]^{0.87} \dots\dots\dots\dots\dots (66b)$$

Chang (Fig. 18(*b*)):

$$G_1 = 480\,600\,n_s\,[T\,(T - T_0)]^{0.74} \dots\dots\dots\dots\dots (66c)$$

O'Brien, for $S = 0.0010$ (Fig. 19):

$$G_1 = 2.4 \times 10^{-5} \left(\frac{V}{R^{\frac{1}{3}}}\right)^{14.4} \dots\dots\dots\dots\dots (66d)$$

O'Brien, for $S = 0.0015$ (Fig. 19):

$$G_1 = 1.8 \times 10^{-6} \left(\frac{V}{R^{\frac{1}{3}}}\right)^{16.0} \dots\dots\dots\dots\dots (66e)$$

and O'Brien, for $S = 0.0020$ (Fig. 19):

$$G_1 = 3.5 \times 10^{-6} \left(\frac{V}{R^{\frac{1}{3}}}\right)^{14.3} \dots\dots\dots\dots\dots (66f)$$

---

[43] "Notes on the Transportation of Silt by Streams," by Morrough P. O'Brien, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, Pt. II, 1936, p. 431.

The MacDougall data resulted in curves having the following equations (illustrations not included):

For $S = 0.0010$ (G_1 plotted against discharge per foot width of flume):

$$G_1 = 40.47\,q - 4.78 \qquad (67a)$$

For $S = 0.0015$:

$$G_1 = 73.20\,q - 6.18 \qquad (67b)$$

and, for $S = 0.0020$:

$$G_1 = 98.62\,q - 6.26 \qquad (67c)$$

in which G_1 = rate of sand movement, in pounds per hour per foot of width.

The general formulas of du Boys, Chang, U. S. Waterways Experiment Station, and MacDougall have been reviewed by the author and further discussion is not necessary. Perhaps it is desirable, however, to discuss briefly the Meyer-Peter formula (Equation (36)) inasmuch as it was developed from measurements on material of uniform granular size. The observations on material ranging from 3.17 mm to 28.8 mm were obtained by the laboratory at Zurich, Switzerland, and from the data of Gilbert.[17] The result of these studies, stated generally by Equation (36), is:

$$\frac{G_2^{2/3}}{D'} = 1.323\,\frac{q^{2/3}\,S}{D'} - 0.335 \qquad (68)$$

in which G_2 is the cubic feet of bed material transported per foot width of channel per second, and D' is the diameter of bed material, in feet. A plot of the data observed at the U. S. Waterways Experiment Station results in the formula $\left(\frac{q^{2/3}\,S}{D'}\text{ plotted against }\frac{G^{2/3}}{D'}\text{; graph not included}\right)$:

$$G_2 = (1.66\,q^{2/3}\,S - 0.147\,D')^{3/2} \qquad (69)$$

Equation (68) was intended primarily for use in movable bed-model studies. The advantage of this relation is obvious when it is noted that dividing both sides by $g^{1/3}$ gives a resulting equation that is non-dimensional and in agreement with the Froude law of similarity.

In flume tests on Columbia River material, Professor O'Brien[43] found that experimental data showed considerable variation when rate of movement was plotted against the following parameters: Velocity at a constant distance from the bottom, mean velocity, the U. S. Waterways Experiment Station method, or the method of Schoklitsch. In all cases the disagreement was greater than could be accounted for by inaccuracy of measurement. Good results, however, were obtained by plotting rate of movement versus $\frac{V}{R^{1/3}}$, as shown in Fig. 19. Professor O'Brien[44] also reported a second method, namely, plotting $\frac{G}{f}$ against $\frac{V}{R^{1/3}}$, that showed slightly less variation than the first.

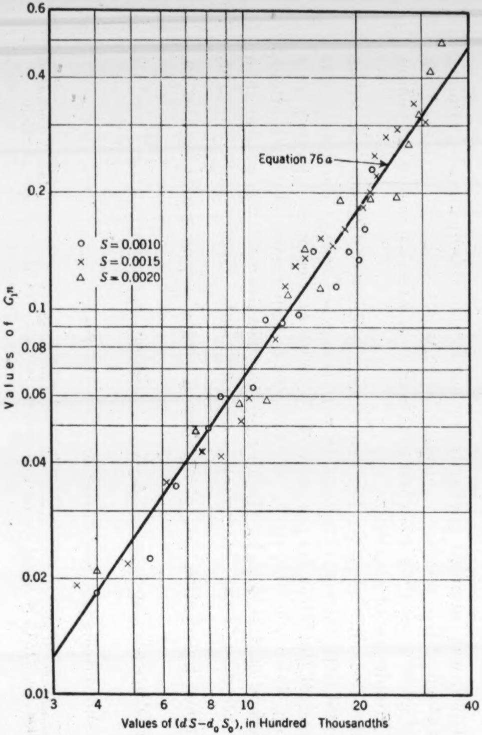

Fig. 17.—Data on Transportation by Traction, According to U. S. Waterway Experiment Station; Equation (39) or Equation (66a)

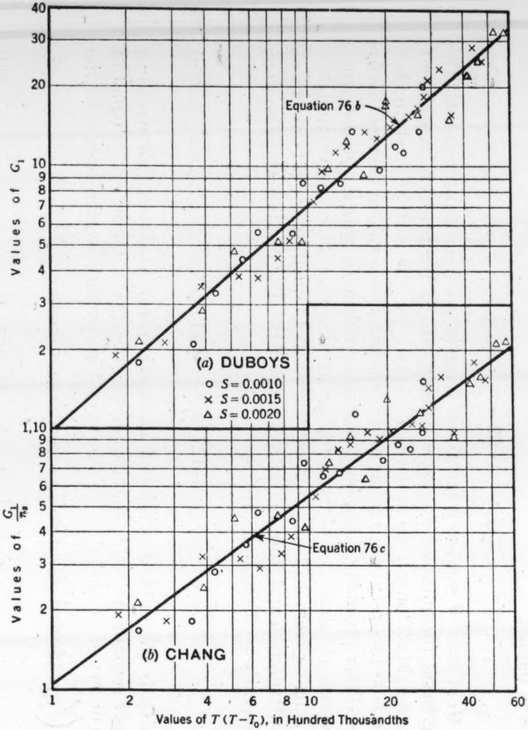

Fig. 18.—Data on Transportation by Traction; Equations (26) and (33)

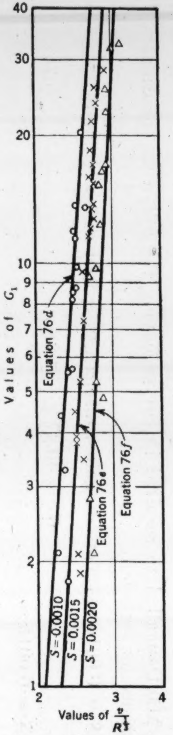

Fig. 19.—Data on Transportation by Traction, According to O'Brien; Equations (66d), (66e), and (66f)

From a glancing examination of the curves shown in Figs. 17, 18, and 19, it is difficult to determine which type of plotting gives the best fit; however, by the application of the χ^2-test, personal opinion is eliminated and an unbiased measure of the goodness of fit is obtained. Table 7 shows values of χ^2 computed for the various criteria. An interpretation of the significance of the computed values of χ^2 requires the use of tables from which the probability of fit can be obtained. Reference to probability tables[45] shows that in 99 out of 100 trials, in random sampling, one should obtain a fit as bad as or worse than that observed, if the real distribution is normal. For these various plots which show such excellent fit, it is to be noted that the probabilities of occurrence are so near the same magnitude that it cannot be truthfully stated that a particular method of plotting is superior to any one of the other methods. The reason for favoring a particular form of plotting, therefore, appears to be only in the ease and accuracy with which certain variables can be measured.

TABLE 7.—COMPARATIVE VALUES OF χ^2

Reference No.	Authority	Number of observations	Values of χ^2	Reference No.	Authority	Number of observations	Values of χ^2
1	U. S. Waterways Experiment Station	52	16	4	Chang	52	23
2	du Boys	52	18	5	Meyer-Peter	52	25
3	MacDougall	52	20	6	O'Brien	52	46

In flume studies there are three sources of error which, in many instances, have seriously limited the value of the results. These sources of error are: (*a*) The use of the water-surface slope instead of the slope of the energy gradient; (*b*) the neglect of the retarding effect of the channel side-walls; and (*c*) the use of relatively short collection periods during which the bed material is trapped. An accurate determination of the slope of the energy gradient requires the measurement of the velocity distribution at each end of the experimental reach. Owing to the relatively short time of a run, this observation is often eliminated and the error involved in slope determination is fairly large for the usual experimental conditions. It is of interest to note that Gilbert[17] was undecided as to the proper value of slope to use and stated:

> "I do not find it easy to decide which slope should be regarded as the true correlative of capacity for traction, but as all our laboratory data include the débris slope, while the determinations of water slope were relatively infrequent, the discussion of the results has adhered almost exclusively to the former. If the water slope is the true correlative, then the use of the débris slope involves a systematic error."

Professor O'Brien and Lieut. B. D. Rindlaub[46] support Gilbert's selection in the statement,

---

[45] "Statistical Methods for Research Workers," by R. A. Fisher, Oliver & Boyd, Lond., 1936.

[46] "The Transportation of Bed Load by Streams," by M. P. O'Brien and B. D. Rindlaub, *Transactions*, Am. Geophysical Union, June 1934, Pt. II, p. 593.

"It is to be noted that the slope of the bottom is more nearly equal to the slope of the energy-gradient than is the slope of the water-surface and partly for this reason, the data of G. K. Gilbert show less scattering than the data of more recent experimenters who have criticized Gilbert for not measuring the slope of the water-surface in all of his experiments."

Consideration of the retarding effect[47] of the channel side walls is necessary in order to correlate the data from flumes of various widths or to correlate accurately the data from a particular flume whose width to depth ratio is relatively small. A striking illustration of the importance of side-wall resistance is afforded by Fig. 20, which shows rates of transportation of Gilbert's Grade *B* sand in flumes of various widths. It is obvious that consideration of side-wall resistance is essential if a general expression for describing rate of transportation by traction is expected. MacDougall[22] attempted to eliminate the effect of the side walls mechanically by placing diversion walls on the experimental flume. Meyer-Peter[20] in his formulation of Equation (36) eliminated side-wall disturbances on the basis of the method given by Einstein.[48] The latter method gives that part of the total discharge which is supposed to be acting upon the bed. The results from Einstein's method are similar to the Schoklitsch[7] method defined by the author in Equation (12). In the data herein discussed, a reduction in scattering of plotted points was not effected by the introduction of α into any of the various parameters used in Figs. 17, 18, and 19.

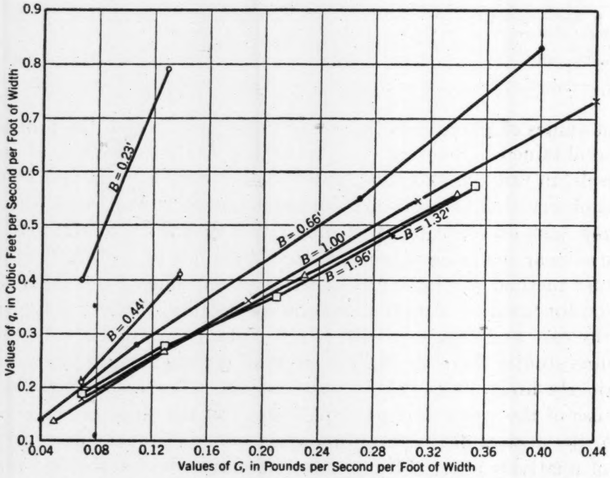

FIG. 20.—DATA ON TRANSPORTATION OF GILBERT'S GRADE *B* SAND IN FLUMES OF VARIOUS WIDTHS; SLOPE = 1 PER CENT

---

[47] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 519.

[48] "Der Hydraulische oder Profil-Radius," by A. H. Einstein, *Schweizerische Bauzeitung*, No. 8, Vol. 103, February 24, 1934.

The use of relatively short collection periods when observing rates of bed-load movement probably accounts for most of the scattering of experimental data. For example, during calibration tests on bed-load traps for use on the Rhine, Einstein[49] observed the rates of bed-load movement shown in Fig. 21.

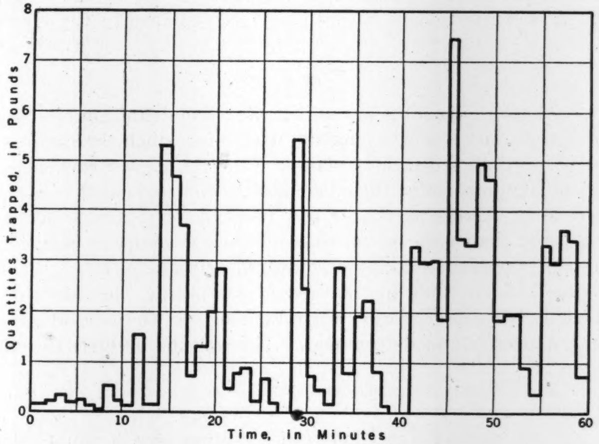

FIG. 21.—TREND OF TRAP RESULTS IN THE COURSE OF ONE HOUR, WITH CONSTANT HYDRAULIC CONDITIONS

It is obvious from an examination of this diagram that relatively long collection periods and recourse to statistical analysis are perhaps necessary to obtain reliable and consistent data on the movement of granular material by flowing water.

J. E. CHRISTIANSEN,[50] ASSOC. M. AM. SOC. C. E. (by letter).—The results of an interesting laboratory study of flume traction and transportation of sediment by suspension, combined with a review of literature on the subject, is presented in this paper. Since the writer has been interested primarily with transportation of silt by suspension, this discussion will deal chiefly with Part III, "Transportation of Material in Suspension."

Equation (49) is derived to express the bottom velocity required to lift a particle from the bed. This assumes that the full impact of the velocity, V_l, is applied in a vertical direction to the projected area of the particle. By definition, the author implies that V_l is the bottom velocity in the direction of flow (horizontal), and not the vertical velocity, or vertical components of the velocity. The derivation of this equation is similar to the usual derivation of an equation for settling velocity of spheres in a fluid,[51] except that the author makes no mention of the coefficient of resistance of the particle, which is unity for particles of only one size. Direct reasoning would indicate that to lift a particle from the bed would require the vertical components of the bottom velocity due to turbulence to exceed the settling velocity of the particle.

[49] "Calibrating the Bed-Load Trap as Used in the Rhine," by A. H. Einstein, *Schweizerische Bauzeitung*, Vol. 110, No. 14.

[50] Asst. Irrig. Engr., Coll. of Agriculture, Univ. of California, Davis, Calif.

[51] "Distribution of Silt in Open Channels," by J. E. Christiansen, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, 1935, pp. 478–485.

In the general formula for the distribution of suspended sediment (Equation (51)), the origin of y must be taken at the point of maximum velocity to be consistent. The Austausch coefficient is correctly defined by the expression,

$$\epsilon = \frac{\tau}{dv \div dy} \qquad \text{(70)}$$

in which τ is the shearing force per unit area. The definition of ϵ as given by the author applies only to a wide shallow stream for which the surfaces of equal velocity are essentially horizontal planes. The Austausch coefficient has the same physical significance for turbulent flow as the coefficient of viscosity has for laminar flow. Assuming that τ is a function of y, any selection for the origin of y, other than point of maximum velocity, indicates a shearing force at the point of maximum velocity and an infinite value of ϵ.

The writer believes that the method of computing the values of ϵ and τ used by Leighly[52, 53] could be used advantageously in the laboratory when the velocity distribution can be determined. This method involves the expression,

$$\epsilon = m\, g\, S \div \frac{dv}{dy} \qquad \text{(71)}$$

in which m is the mass of water between a unit surface of equal velocity and the region of maximum velocity, bounded on the sides by surfaces normal to the surfaces of equal velocity.

The author states (see "Experimental Verification") that "tests have been made on sediment distribution as described; the results plotted do not agree with the theoretical Equation (51) because this equation is presumably derived for a considerably wide channel suffering no side restrictions." This statement appears misleading because no such assumptions are made in its derivation.[54] The only assumptions concern the evaluation of ϵ. For a deep narrow flume, ϵ is not correctly expressed by the equation given by the author. From the subsequent remarks, it appears that the exponential curve did fit the observed data when a coefficient was applied to the exponent. Another factor that may have affected the value of the exponent, $\omega\, \rho \int_0^v \frac{dy}{\epsilon}$, is a possible error in the value of ω. Although Rubey's equation appears to fit Richards' experimental data[55] very well, it should be noted that Richards determined the size of the particles by means of sieves. Knapp[56] and Alexander

and Jacob[57] have reported that settling velocities of particles computed from microscopic measurements of diameters are too high, and that they agree better with data on spheres when diameters are determined with sieves.

Concerning the size of particles, the author states (see "Part I," heading, "Mechanical Properties of Test Samples"), "for fine grains the volume of which was not measurable, D was assumed equal to the mean of D_1 and D_2." For Samples 6198 and 6197, however, the value of D as given in Table 1 is the same as for D_2. The writer has been unable to check the values of ω given from the formula and values of D as given in Table 1, or from the mean value of D_1 and D_2. It appears possible that the difficulty in making the equation fit the experimental data might be due, at least partly, to incorrect determinations of both ϵ and ω. In the writer's study[58] it appeared that Equation (51) was in very good agreement, without modification, with all the available published data that were analyzed.

The author's discussion of total load in suspension is interesting, but it must be kept in mind that these equations are valid only for silt particles with a uniform settling velocity. Silt found in suspension in natural streams includes particles of various sizes and settling velocities. For each size fraction, the concentration at any depth can be expressed by Equation (51) in terms of the known concentration at one depth, the turbulence of the stream as expressed by ϵ, and the settling velocity of the silt, ω. The total concentration of all size fractions cannot be expressed by a similar exponential equation, however, and, consequently, the total load in suspension is not correctly expressed by Equations (56) to (59).

Assume a general case of a natural stream for which the vertical velocity distribution is determined with a current meter, and a sample of silt is collected at one or more depths. The silt samples can be analyzed for distribution of size of particles, and a curve can be plotted showing this relationship graphically. The average settling velocity for each size fraction between rather narrow limits can be estimated. From the velocity distribution, $\frac{dv}{dy}$, and slope, S, values of ϵ can be determined by graphical integration. Curves can then be constructed showing the size distribution of silt in a vertical section for each size fraction. The total concentration at any depth is, $c_T = c_1 + c_2 + c_3 + \cdots$, in which c_1, c_2, etc., are the concentrations for each size fraction. A curve for c_T plotted against y can then be plotted, but the relationship cannot be expressed by a simple exponential equation. The total load, P, is correctly expressed by the relation,

$$P = \int_0^d c_T \, v \, dy \ldots\ldots\ldots\ldots (72)$$

and the integration can be performed graphically.

[57] "Mechanical Analysis of Finely Divided Natural Phosphates," by L. T. Alexander and K. D. Jacob, *Technical Bulletin 212*, U. S. Dept. of Agriculture, 1930, pp. 1–24.

[58] "A Study of the Distribution of Silt in Open Channels," by J. E. Christiansen, Assoc. M. Am. Soc. C. E. Thesis submitted in partial fulfillment for the degree of Civil Engineer, Univ. of California, 1935. (Not published; on file in the Library, Univ. of California.)

The writer questions the validity of Equation (61) and the reasoning that precedes it. He can see no more reason for assuming that the kinetic energy of a stream is independent of the silt carried, than for first assuming that the velocity is not affected. It would seem that the principal effect of silt on the velocity and kinetic energy would be due to a possible change in the smoothness of the bed, and the possible effect on the Austausch coefficient, ϵ. Few data are available on this point. Buckley[59] observed that the velocity increased during periods of high silt concentration, other factors remaining constant. In deriving the general expression for silt distribution, the basic assumption is made that ϵ is not a function of silt concentration; and this assumption is probably justified for ordinary concentrations found in many rivers, but it may not be justified for the exceptionally high concentrations sometimes found.

Referring to the "Summary," Part III, the writer cannot agree with Conclusions (1), (3), (4), and (5). The reasoning leading to Conclusion (1) does not appear sound for the reasons previously mentioned. In connection with Conclusion (2), it must be kept in mind that Equation (51) expresses the relationship only for a single-size fraction, and that the distribution curve for a graded silt is not a simple exponential curve. Conclusion (3) is misleading. The first part of the expression, Equation (55), $c_m = \frac{1}{d}\int_0^d c\,dy$, is valid, but the latter part of the expression applies only to the specific case of parabolic velocity distribution, and maximum velocity at the surface, where it is seldom found. The statement concerning the location of the point of mean silt concentration is based on a calculation for specific conditions, and does not hold, generally. For the assumptions used by the author, a general expression for the position of the mean silt concentration in a vertical section can be obtained by equating,

$$e^{\alpha y} = \frac{1}{d}\left(e^{\alpha d} - 1\right) \qquad \text{(73a)}$$

from which,

$$y = \frac{1}{\alpha}\ln\left(\frac{e^{\alpha d} - 1}{\alpha d}\right) \qquad \text{(73b)}$$

The position of mean silt concentration, therefore, is a function of α as well as d. Furthermore, the use of the term, "mean silt concentration," to refer to the average silt concentration in a vertical section is misleading. Mean silt concentration is more properly defined by the expression,

$$c_m = \frac{P}{q} \qquad \text{(74)}$$

The total amount carried in a vertical section of uniform width is expressed correctly by the equation,

$$P = \int_0^d c\,v\,dy \qquad \text{(75)}$$

[59] "The Influence of Silt on the Velocity of Water Flowing in Open Channels," by A. B. Buckley, *Minutes of Proceedings*, Inst. C. E., Vol. 216 (II), 1922–23, p. 183.

in which both c and v are functions of y. The first statement in Conclusion (4) is not verified by the data presented. The second statement is valid only for a single size fraction, and cannot be applied to the total silt concentration of a stream. Conclusion (5) is the result of an assumption that may not be valid, and is in direct conflict with certain previous observations.

W. H. **Huang**,[60] Esq. (by letter).—The lucid explanations which the author has given to some of the phenomena observed in his experiments are impressive. For example, he interprets Exponent β in Equation (20) and Equation (21*c*) as turbulence, and shows that sorting will take place in graded sands irrespective of the mode of motion of the particles, and that the coarser particles will move in greater quantities than the finer ones.

Attention is called to Equation (13), in which it appears that the term corresponding to the decrease in potential energy is incorrect. Mr. Chang takes the average of the drop of the water surface and that of the bed in the reach, dx, as the decrease in potential energy, and thus he obtains $w\,y\,\frac{\sin\alpha + \sin\alpha_0}{2}\,dx$. It is known, however, that throughout the depth at any section the potential energy is equal to that at the water surface. The decrease in potential energy, therefore, should be: $w\,y\cos\alpha_0\tan\alpha\,dx$; and Equation (13) should read:

$$\frac{w\,y}{2\,g}\left[(V + dV)^2 - V^2\right] + T\,dx = w\,y\cos\alpha_0\tan\alpha\,dx \quad\ldots\ldots(76)$$

In deriving Equation (15) Mr. Chang refers to Fig. 5, which is also incorrect. Taking x as positive toward the right and y as positive upward, the depth of water at the left section should be taken as y, and the increment of depth at the right section should be taken as $(-)\,dy$. Using these correct notations, $\frac{dV}{dy} = \frac{-V}{y}$, $\frac{(-)\,dy}{dx} = \cos\alpha_0\tan\alpha - \sin\alpha_0$, is obtained and,

$$T = \left[w\,y\cos\alpha_0\tan\alpha + w\,\frac{V^2}{g}(\sin\alpha_0 - \cos\alpha_0\tan\alpha)\right] \quad\ldots\ldots(77)$$

For a sloping bed with uniform flow,

$$T = w\,y\sin\alpha_0 \quad\ldots\ldots\ldots\ldots(78a)$$

and, for a horizontal bed,

$$T = w\tan\alpha\left(y - \frac{V^2}{g}\right) \quad\ldots\ldots\ldots\ldots(78b)$$

Therefore, for great depth with comparatively small velocity, the tractive force on a horizontal bed is approximately equal to that on a sloping bed with the same water-surface slope (not 0.5 as the author has concluded). Therefore, the values of T_0 in Table 4 should be recalculated, and Equation (20) should be modified accordingly.

---

[60] Prof. of Hydr. Eng., National Central Univ., Chungking, China.

Equation (76) may also be considered as Bernoulli's equation with each term multiplied by the factor, $w\,y$; thus:

$$T\,dx = w\,y\,H_f \quad \text{.......................} (79)$$

in which H_f is the loss of head in the reach, dx.

Since,

$$H_f = S_e\,dx \quad \text{.......................} (80)$$

in which S_e is the energy gradient; therefore:

$$T = w\,y\,S_e \quad \text{.......................} (81)$$

By Manning's formula,

$$S_e = \frac{n^2\,Q^2}{2.21\,y^{3.33}} \quad \text{.......................} (82)$$

which, substituted in Equation (81), yields,

$$T = \frac{w\,n^2\,Q^2}{2.21\,y^{2.33}} \quad \text{.......................} (83)$$

or,

$$T = w\,y\sin\alpha_0\left(\frac{y_0}{y}\right)^{3.33} \quad \text{.......................} (84)$$

in which y_0 is the depth of normal flow.

For channels other than the rectangular cross-section of infinite width as assumed, the average tractive force may be represented by the following formula: $\bar{T} = w\,R\,S_e$; or,

$$\bar{T} = \frac{w\,n^2\,Q^2}{2.21\,R^{\frac{1}{3}}\,A^2} \quad \text{.......................} (85)$$

Equation (85) may be used to calculate the tractive force in experimental flumes where the walls are roughened to give approximately the same roughness as that of the bed. When the roughness of the walls differs widely from that of the bed, as in the author's flume, more experimentation is needed to justify the use of Equation (4) and Equation (6).

LORENZ G. STRAUB,[61] ASSOC. M. AM. SOC. C. E. (by letter).—Many differences of opinion have been expressed from time to time relative to the transportation of sedimentary materials by rivers. Laboratory studies have aided in arriving at conclusions, but even in that case there is lack of agreement between various investigators. The author has presented an interesting review of several noteworthy studies which have appeared in engineering literature during the past several years; he also compares results of his own observations with results of earlier investigators. He is to be commended on his approach to the problem and his effort to give due consideration to the dimensional analysis of his theories. However, the writer cannot agree with the logic of some points in the theoretical development and the author's conclusions. He is, therefore, taking the liberty of discussing a few of these questions in some detail, without, however, giving special consideration to other features of the paper.

---

[61] Prof. of Hydraulics and Administrative Asst., Coll. of Eng. and Architecture, Univ. of Minnesota, Minneapolis, Minn.

The data pertaining to the relation between Manning's n and size of particles are of considerable interest. They conform very closely to results obtained in connection with studies by the writer for roughness factors in laboratory experiments on sediment transportation. Of course, in case of a lack of uniformity of motion of the bed material (as, for example, when pronounced riffle formation takes place) there is considerable change in the value of the roughness coefficient. Presumably, the author's data are for relatively low velocities.

Exception is taken to the analysis of the "effect of non-uniform flow on tractive force." Equation (17) and the conclusions drawn therefrom appear to be illogical and seem to be mathematically unsound. Although the traction force can be written (as is usually the procedure) as a function of the water-surface slope, depth, and unit weight of the water, this conception is useful primarily as a simple means of visualizing tractive force in the case of uniform flow. Tractive force can be written in terms independent of the slope of the water surface or of the stream bottom, if due account is taken of the roughness of the bed and the velocity of the stream.[62] Subsequently, the writer will indicate one possible relation of this character, showing that for a given roughness and velocity of flow the traction force is independent of the slope of the stream bottom.

Apparently, the author assumes that Equation (15) is correct because for the special case of a sloping bed with uniform flow the usual expression for traction force is obtained. However, although the equation for the special case happens to reduce to the correct form, the general form (Equation (15)) is mathematically incorrect.

Detailed consideration will now be given to Equation (17). Assume that super-critical velocity takes place. In the case of a horizontal bed the value of S must be negative. Equation (17) would thus indicate a negative tractive force or consequent sediment transportation in a direction opposite to that of the flow of the water. Other similar illogical deductions would result from a close analysis of the physical significance of the relation. A careful analysis of the type suggested by the author for a horizontal bed will lead to the equation:

$$T = w\,S\left(y - \frac{V^2}{g}\right) \ldots\ldots\ldots\ldots\ldots\ldots (86)$$

instead of the expression represented by Equation (17). Here, in the case of super-critical flow (shooting velocity), S likewise becomes negative, but the expression in the parentheses becomes negative simultaneously, so that the value of T remains positive. It is impossible for flow to go through the energy critical on a horizontal bed. For this hypothetical condition in Equation (86), mathematically the value in parentheses $\left(y - \frac{V^2}{g}\right)$, would become zero and the slope, S, would become infinite; this conforms to the physical phenomenon just mentioned. In the case of non-uniform flow on a horizontal bed of infinite width the slope of the water surface in the Manning formula might be expressed as:

---

[62] "Hydraulic and Sedimentary Characteristics of Rivers," by Lorenz G. Straub, *Transactions*, Am. Geophysical Union, Thirteenth Annual Meeting, National Research Council, 1932, pp. 375–382.

$$S = \frac{V^2}{C^2\, y^{\frac{1}{3}} \left(y - \frac{V^2}{g} \right)} \dots\dots\dots\dots\dots\dots (87)$$

in which the value of C corresponds to the expression, $C = \frac{1.486}{n}$, in Manning's formula. Substituting this value for the slope of the water surface into Equation (87) it will be found that:

$$T = w\, \frac{V^2}{C^2}\, \frac{1}{y^{\frac{1}{3}}} \dots\dots\dots\dots\dots\dots (88)$$

Thus, the traction force is shown to be a function of the velocity, depth, and roughness. The expression for the traction force in Equation (88) is the same as would be obtained by substituting from Manning's formula for uniform flow the value of $S = \frac{V^2}{C^2\, y^{\frac{4}{3}}}$ into the equation for tractive force for uniform flow, $T = w\, S\, y$.

The use of narrow channels in the experimental study of the effect of tractive force upon sediment transportation invariably involves certain limitations and necessitates corrections due to side-wall effects. The writer has experienced considerable difficulty in this regard even in the case of channels as wide as 12 in. Unless corrections are made for side effects the results are likely to be appreciably in error.

Reference is here made to the analytical treatment of the observations as indicated in Table 3. The side influence has been taken into account in computing the water-surface slope in Column (11). However, the computation for the tractive force (Column (13)) is incorrect, first in that Equation (17) was used and, second, in that the traction on the side walls has been neglected. Computation by Equation (17) gives tractive forces on the stream bed which are too low, while neglecting the resistance due to the sides of the channel gives an indicated tractive force which is too high. These two errors of opposite sign in this particular case have a more or less counter-balancing influence upon the result, so that the tractive force indicated in the tabulation seems to be in the proper order of magnitude. Nevertheless, if the results are scrutinized it will be observed that the computed critical tractive force for sediment transportation is indicated in the tabulation to be greater for the deeper streams of water. This is due to the fact that the traction resistance on the sides of the channel has greater influence as the depth of flow increases.

In connection with extensive experimental work on sediment transportation the writer has observed the phenomena noted by the author relative to an apparent change in the law of transportation for finer sediments. The change is similar to that indicated by the author; however, thus far an abrupt critical from one law to another has not been noted. A change somewhat of the type indicated in Fig. 6 seems likely although the critical point does not seem to be accurately defined by experimental results. In the writer's opinion the visual determination of traction force is likely to be unsatisfactory for use in the application of the du Boys formula for determining the quantity of material transported. It will be found that the introduction of a value for the critical tractive force or its equivalent in terms of the velocity, roughness, and hydraulic radius of the stream into some form of the du Boys formula (which is considerably different from that usually recorded from direct observation) will more nearly correspond to the actual movement of the sedimentary load. This has been previously cited by the writer in connection with studies of the sedimentary characteristics of the Missouri River.[63] It is generally found that the observed critical tractive force indicating "general motion" recorded by most observers is too low to give best results in the application of the du Boys formula. A typical example is indicated in Fig. 22, which represents the comparison of actual sediment transportation observed by Schaffernak,[64] with a theoretical analysis by the writer. The theoretical curves in Fig. 22 are plotted only for two of the series of samples tested by Schaffernak. It is interesting to note that although the experiments by Schaffernak were made with water flowing at super-critical velocities, the same theoretical analysis was applicable as for sub-critical velocities, provided due account is taken of the proper roughness factor for the particular material concerned.

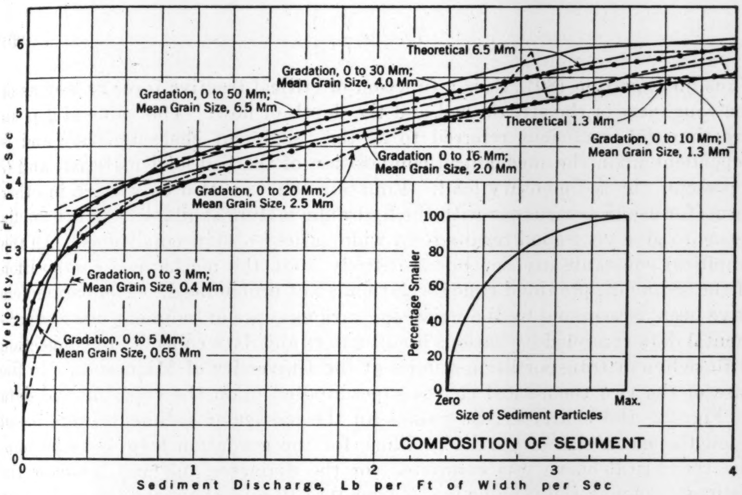

FIG. 22.—COMPARISON OF BED SEDIMENT TRANSPORTATION THEORY WITH SCHAFFERNAK EXPERIMENTS

The theoretical curves in Fig. 22 were computed using the following formula derived by the writer for bed-load transportation:

$$G = \psi\, C^{-4}\, d^{-\frac{3}{4}}\, V^2 \left(V^2 - V_0^2\right) \ldots\ldots\ldots\ldots\ldots\ldots (89)$$

---

[63] "Missouri River Report," Appendix XV, U. S. Serial No. 9829, H. R. Doc. No. 238, 73d Cong. 2d Session.

[64] "Neue Grundlagen für die Berechnung der Geschiebeführung in Flussläufen," by Dr. F. Schaffernak, 48 pp., Franz Deuticke, Leipzig and Vienna, 1922.

in which C corresponds to the coefficient in Manning's formula—that is, $C = \frac{1.486}{n}$; d is the depth of flow; and V is the velocity of flow. The value of V_0 is determined from experimental data and corresponds approximately to the velocity at which transportation begins when computed by the relation,

$$T = w \frac{V^2}{C^2} \frac{1}{d^{\frac{1}{3}}} \quad \text{(90)}$$

Thus, in Equation (89), V_0 is a function of critical tractive force as well as of the roughness of the stream bed and the depth of flow. The value of ψ is an experimental coefficient referred to as the "sediment characteristic" and is dependent upon the mechanical composition of the bed-load material; and G represents the sedimentary load. Equation (89) can also be written in other forms for use in accordance with the hydraulic factors available. The formula seems to give very good results for a wide variety of flow conditions. All the empirical constants are dependent entirely upon the mechanical composition of the sediment, provided riffle formation is not pronounced. The parameters have been determined by the writer for various types of sediment using experimental data compiled by various investigators and data collected in connection with sediment transportation studies at the University of Minnesota. In the case of the two theoretical curves superimposed upon the experimental data in Fig. 22, the characteristic values for the particular sediments were based upon the mean size of particle. Thus, for the gradation from 0 to 50 mm, the theoretical curve was computed for the diameter, 6.5 mm, and for the sedimentary material ranging in size from 0 to 10 mm, the mean size of 1.3 mm was used. For the coarser material, $\psi = 28\,000$, where G is measured in pounds per second per foot breadth of channel; $T_0 = 0.115$ lb per sq ft; and $n = 0.021$. In the case of the curve for the finer material the values are $\psi = 92\,000$, $T_0 = 0.0275$, and $n = 0.0165$. It should be noted that the critical velocity, V_0, at which sediment transportation begins is a function of the depth and roughness as well as of the critical tractive force, the latter being determined from data on rates of sediment transportation rather than simply being a visual determination of the beginning of sediment movement.

There are certain difficulties involved in any theoretical analysis when the riffle formation becomes a major importance. The difficulty appears to be primarily in the formulation of an accurate value for the roughness coefficient. This is particularly true in the case of shallow depths of flow. There are different modes of transportation when riffles form. Three types of bed-load movement can be clearly distinguished. In one instance, riffles progress forward after the fashion of sand dunes, practically all particles coming to resent periodically when reaching the leeward side of the dune. For this case the writer has found that the bed-load can be computed readily by simply taking into account the shape, height, and velocity of the riffles. Another extreme is the condition under which no riffles form—that is, when the bed is quite smooth. For this case the roughness coefficient has been reasonably well fixed and the bed-load can be computed with a reasonable degree of accuracy. There is an intermediate condition between these two extremes in which undulations or riffles of a rounded form appear on the surface of the bed.

Here there is a progressive movement of the riffles, but there is also general movement of the stream bed. Computation based solely on the height, shape, and speed of the riffle in such instances is found to give a sedimentary load less than the actual load. These different formations are related at least in part to the Froude number for the condition of flow. Thus, for a Froude number of unity or flow near the energy (velocity) critical, very pronounced dune-type riffles will frequently be observed with certain types of sand. The mechanical composition of sand also influences the character of the sediment transportation.

Hunter Rouse,[65] Assoc. M. Am. Soc. C. E. (by letter).—A comprehensive treatment of sediment transportation is not an easy task, for at the present time the subject is in a pronounced state of flux. Moreover, for want of more conclusive experimental evidence, every man's opinion seems to differ from that of the next. The writer, therefore, confines his remarks to one portion of the author's mathematical derivation and to several phases of the general problem which warrant amplification in the light of research results not mentioned in the paper.

Perhaps the safest way to arrive at a general equation for tractive force is to follow the development of the energy equation for gradually varied flow. The basic expression,

$$E = \frac{V^2}{2\,g} + y + h_0 \dots\dots\dots\dots\dots\dots\dots (91)$$

is usually differentiated with respect to distance in the direction of flow:

$$\frac{dE}{dx} = \frac{d\left(\frac{V^2}{2\,g}\right)}{dx} + \frac{dy}{dx} + \frac{dh_0}{dx} \dots\dots\dots\dots\dots\dots (92)$$

The term at the left then represents the local rate of change of total head. Designating a downward slope as positive, $-\frac{dE}{dx}$ will equal S_e, the slope of the energy line. For want of accurate knowledge as to the rate of energy loss in gradually varied flow, this slope is necessarily assumed to be the same as that for uniform flow at the same mean velocity and depth;[66] thus,

$$S_e = \frac{V^2}{C^2\,y} \dots\dots\dots\dots\dots\dots\dots\dots (93)$$

The error involved in this assumption is probably not serious, in particular if the flow is in the tranquil state. Such an assumption as to the rate of energy loss is tantamount to making the boundary shear equal to that in uniform flow for the same values of y and V, because, regardless of how the rate of energy dissipation may be distributed over the flow section, the resulting shearing stresses are transmitted undiminished to the fixed boundary. It then follows that,

---

[65] Associate Hydr. Engr., Soil Conservation Service; Asst. Prof. of Fluid Mechanics, California Inst. of Technology, Pasadena, Calif.

[66] "Hydraulics of Open Channels," by B. A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph Series, McGraw-Hill Book Co., 1932, p. 25.

$$\frac{dE}{dx} = -S_e = -\frac{V^2}{C^2 y} = -\frac{T}{w y} \qquad (94)$$

The second term of Equation (92), showing the rate of change of velocity head, is written in terms of depth and mean velocity as follows:

$$\frac{d\left(\frac{V^2}{2 g}\right)}{dx} = \frac{d\left(\frac{q^2}{2 g y^2}\right)}{dx} = -\frac{q^2}{g y^3}\frac{dy}{dx} = -\frac{V^2}{g y}\frac{dy}{dx} \qquad (95)$$

The third and fourth terms may be combined to yield the slope of the water surface,

$$\frac{d(y + h_0)}{dx} = -S_w \qquad (96)$$

while the fourth term alone represents the slope of the channel bottom:

$$\frac{dh_0}{dx} = -S_0 \qquad (97)$$

Upon introducing these several equivalent values, the differential equation may be rewritten with the intensity of boundary shear as the dependent variable:

$$T = w\, y\left(\frac{V^2}{g\, y}\frac{dy}{dx} - \frac{dy}{dx} + S_0\right) \qquad (98)$$

Equation (98) is the general expression for tractive force in gradually varied flow, and is recommended in place of the author's Equation (15).

In the case of non-uniform flow in a horizontal channel—under which condition the author's experiments were conducted, $-S_0$ is zero and $\frac{dy}{dx}$ becomes equal to $-S_w$; whereupon.

$$T = w\, S_w\left(y - \frac{V^2}{g}\right) \qquad (99)$$

Equation (99) should replace the author's Equation (17).

Since the author so evidently sought to present an inclusive résumé of past research in this field, it is unfortunate that he failed to include a very valuable paper by A. Shields[67] which successfully answers more than one troublesome question touched upon in the paper. In this investigation it was shown that the relative magnitudes of tractive force and the resistance to motion of uniform sediment grains could be expressed dimensionlessly in the form, $\frac{T}{(\sigma - \rho)\, w\, D}$. (The writer presumes, despite evidence to the contrary, that the author's symbols for specific gravity of sediment and fluid, σ and ρ, have their usual dimensionless significance, as distinguished from w, the specific weight of water.) This ratio, therefore, represents a fundamental parameter in bed-load movement, subject to the possible inclusion of additional factors for shape and grading of the material. Through comparison with Nikuradse's analysis of flow in artificially roughened pipes,[68] it was then proved that the beginning of movement from a leveled bed of uniform grains should depend upon a single additional parameter, $\sqrt{\frac{g\,T}{w}}\frac{D}{\nu}$. This parameter, furthermore, is proportional to the ratio of grain diameter to boundary-layer thickness, and as such has already been used to co-ordinate the measurements of pipe resistance for various conditions of relative roughness.[69] In other words,

[67] "Anwendung der Aehnlichkeitsmechanik und der Turbulenzforschung auf die Geschiebebewegung," by A. Shields, Mitteilungen der Preussischen Versuchsanstalt für Wasserbau und Schiffbau, Heft 26, Berlin, 1936. Translations are on file at the Engineering Societies Library, 33 West 39th Street, New York, N. Y.; National Hydraulic Laboratory, Washington, D. C.; and the U. S. Waterways Experiment Station, Vicksburg, Miss.

$$\frac{T_0}{(\sigma - \rho)\,w\,D} = \varphi\left(\frac{D}{\delta}\right) \quad\ldots\ldots\ldots\ldots\ldots\ldots (100)$$

Shields made careful measurements of initial movement on beds of pulverized amber, lignite, granite, and barite, each of uniform size, and plotted his results dimensionlessly—together with those of other investigators using sand—as shown in Fig. 23. Despite considerable variation in specific gravity, diameter, and conditions of flow, the plotted values are seen to follow a single functional trend. At the left the laminar boundary layer still envelopes the particles on the bed, and the initial motion is not dependent upon turbulence; conditions of flow are, therefore, similar to those along a smooth boundary. When the particles begin to protrude through the laminar layer, initial effects of boundary roughness are noticeable, and the curve gradually approaches a minimum value. An upward trend begins when particles become sufficiently large to disrupt the laminar flow around them. An asymptotic limit is finally reached when the boundary layer no longer exists, owing to the turbulent wake produced by bed roughness of relatively great magnitude. The form of the curve closely approximates that resulting from Nikuradse's measurements on rough pipes.[68, 69]

Although the problem of initial movement has also been approached in terms of boundary-layer thickness by W. W. Rubey[70] and others, Shields' analysis appears to provide the solution sought by Professor Chang (compare with Figs. 6 and 7). Shields further noted that the relative dimensions of D and δ also govern the form of the initial bed irregularities. Particles moving within the laminar layer show a pronounced tendency to form ripples. Sediments slightly disrupting the boundary layer form "scales"—that is, longer, lower ripples. The ratio of length to height of the bed undulations increases steadily with the parameter, $\frac{D}{\delta}$, until finally the entire surface of the bed moves fairly uniformly as the curve of initial motion approaches its horizontal asymptote.

In Fig. 23 values of the bed-load parameter greater than the minimum evidently represent stages of movement beyond the initial phase. Shields, therefore, used this parameter in the form, $\frac{(T - T_0)}{(\sigma - \rho)\, w\, D}$, to develop an equation for rate of transport. The remaining dimensionless parameter is composed of the ratio of weight discharges of sediment and water, the specific gravities of sediment and water, and the slope. In order that the viscosity may have no appreciable influence upon the movement, the analysis is restricted to conditions in which the ratio of height to length of the bed undulations is low. Measured rates of movement for the five different types of material, plotted in Fig. 24, are seen to follow the equation,

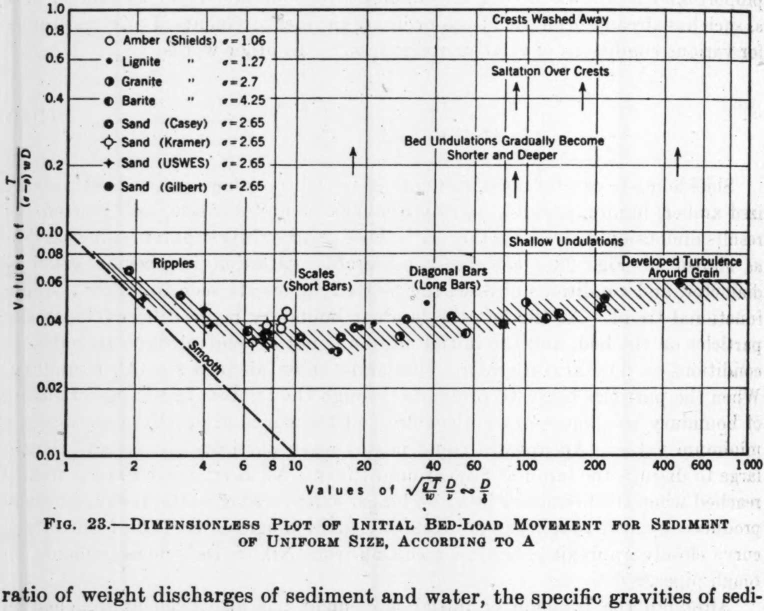

FIG. 23.—DIMENSIONLESS PLOT OF INITIAL BED-LOAD MOVEMENT FOR SEDIMENT OF UNIFORM SIZE, ACCORDING TO A

$$\frac{G}{Q\,S}\,\frac{\sigma - \rho}{\rho} = 10\,\frac{T - T_0}{(\sigma - \rho)\, w\, D} \qquad (101)$$

over nearly a thousand-fold range on either scale. The scattering of points, so characteristic of experimental results of this nature, is attributed to long-period cycles of bed movement; in addition, points for shooting flow lie somewhat higher than the others. This relationship is not to be considered an ultimate statement of bed-load transport, for the influence of shape and grading of the sediment grains still remains to be determined.

With regard to the author's treatment of suspended load, the writer would call attention to the fact that the validity of Equation (51) has been proved experimentally.[71] On the other hand, it remains to be seen whether the magnitude of ϵ determined from the velocity gradient in turbulent flow will correspond numerically to that for the sediment concentration at the same elevation. Otherwise, abundant evidence of a logarithmic velocity distribution in wide channels would seem to justify the form of the suspended load function published by the writer.[32]

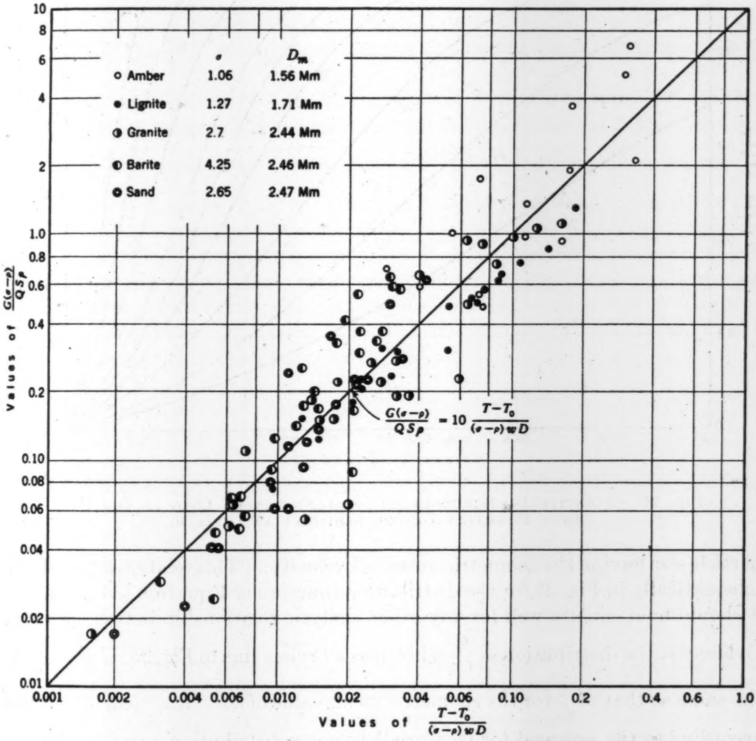

FIG. 24.—DIMENSIONLESS PLOT OF BED-LOAD TRANSPORTATION FOR SEDIMENT OF UNIFORM SIZE, ACCORDING TO A

The author attempts to integrate a simplified distribution function in order to express the total suspended load carried by a given flow—the total load, that is, of a given particle size. Obviously, in the case of a graded sediment, the process must be repeated for every different size. It is possible to simplify this procedure for specific conditions in a manner which may also prove to have general application. If the fall velocities of the various sizes of sediment at the level, *a*, follow a normal distribution curve (that is, linear when plotted on logarithmic probability paper), the ratio of total concentration, C, at any higher level to that at the level, *a*, will follow closely the distribution curve for the

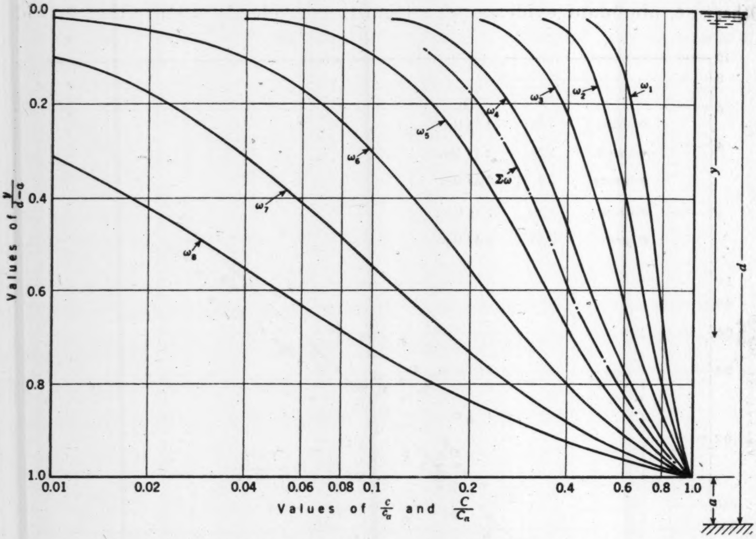

FIG. 25.—RELATIVE DISTRIBUTION OF TOTAL SUSPENDED LOAD IN THE CASE OF A NORMALLY GRADED SEDIMENT AT LEVEL *a*

particle size having the geometric mean fall velocity. This relationship is shown schematically in Fig. 25 for the distribution function of Equation (54), although it should hold equally well for any other analytic relationship between ϵ and y. Evidently, the distribution of $\frac{C}{C_a}$ (shown as a broken line in Fig. 25) is practically the same as that of $\frac{c}{c_a}$ for the geometric mean value of ω. Graphical integration according to the assumed (or measured) velocity distribution curve would then be a relatively simple matter.

Y. L. CHANG,[72] ESQ. (by letter).—The valuable criticisms and ingenious contributions to the discussion have been of great benefit. Captain Kramer does not agree on the hypothesis of the tractive force on the stream bed by a non-uniform flow. The writer believes, however, that the investigation of the influence of non-uniform flow (although it complicates the problem) is undoubtedly necessary in order to study the actual condition of debris transportation in natural water courses. In the derivation of the expression for the decrease of potential energy, the same correction has been made independently by Professors Huang, Straub, and Rouse, and a revised conclusion has been drawn regarding the tractive force due to an accelerating flow in a horizontal channel bottom. The writer derived these equations on the basis of certain assumptions and certain reasoning which were not given in detail in the paper.

---

[72] Associate Prof. of Civ. Eng., Tsing Hua Univ., Yunnanfu, Yunnan, China; and Cons. Engr. to the Provincial Government of Kweichow, Kweiyang, Kweichow, China.

First, the writer considers the acceleration due to a convergence of stream lines in a non-uniform flow. The hypothesis is shown diagrammatically in Fig. 26. Professor Bakhmeteff has stated[73] that "when the stream lines are substantially inclined toward the cross-sectional plane, the acceleration *o a* may have a noticeable component *o a′* in the cross-sectional plane, the effect of which again will be to modify the distribution of pressures as caused by gravity alone." In the writer's derivation of the expression of potential energy between the stretch dx a mean excessive pressure of $\frac{w\,dy}{2}$ exerted on the down-stream cross-sectional plane is included. Moreover, Professor Bakhmeteff definitely shows that "elementary hydromechanics teaches that the distribution of pressure in a cross-section of moving fluid will obey the hydrostatic law and will be affected solely by gravity, when, and only when, flow takes place in such a manner that the fluid filaments have no acceleration components in the plane of the cross-section." Therefore, in the case of accelerated flows, it is obviously unsound to conclude that throughout the depth at any section the potential energy is equal to that at the water surface.

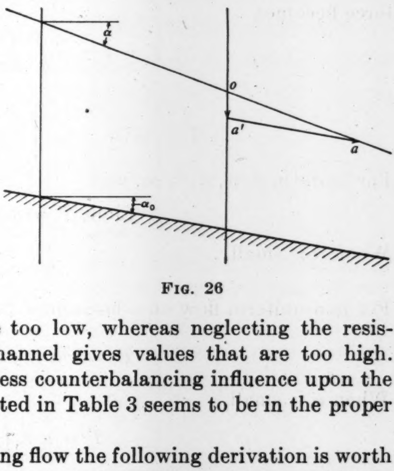

FIG. 26

Secondly, the experimental results of tractive force obtained in this particular flume are more likely consistent with the foregoing theory. However, this has been clarified by Professor Straub in his discussion that computation by Equation (17) gives values of tractive force that are too low, whereas neglecting the resistance due to the side-wall of the channel gives values that are too high. These two deviations have a more or less counterbalancing influence upon the result, so that the tractive force indicated in Table 3 seems to be in the proper order of magnitude.

In illustrating the effect of converging flow the following derivation is worth studying. Let *A B* in Fig. 27 be a short stretch, within and near which the surface curve can be considered as a straight line with a slope α, and converges with the bottom at an angle $(\alpha - \alpha_0)$. The section that approximates the equipotential section at Point *A* most reasonably is an arc *A c* struck with Line *A C* as a radius. Call this arc length s; then,

$$s = r\,(\alpha - \alpha_0) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (102)$$

---

[73] "Hydraulics of Open Channels," by B. A. Bakhmeteff, M. Am. Soc. C. E., Engineering Societies Monographs, 1932, p. 29.

in which r is the radius. The relationship between the vertical depth y and s could be formulated thus:

$$\overline{A\,c} = y \frac{\cos\alpha}{\cos\left(\frac{\alpha - \alpha_0}{2}\right)} \qquad \text{.......... (103)}$$

$$r = \frac{\overline{A\,c}}{2} \frac{1}{\sin\left(\frac{\alpha - \alpha_0}{2}\right)} \qquad \text{.......... (104)}$$

and,

$$s = \frac{y}{2} \frac{(\alpha - \alpha_0)\cos\alpha}{\sin\left(\frac{\alpha - \alpha_0}{2}\right)\cos\left(\frac{\alpha - \alpha_0}{2}\right)} = \frac{y\,(\alpha - \alpha_0)\cos\alpha}{\sin\,(\alpha - \alpha_0)} \qquad \text{.... (105)}$$

Equating the energy expressions:

$$\frac{w}{2\,g}\left[(V + dV)^2 - V^2\right] + \frac{T}{s}\,dx = w\,dx\sin\alpha \qquad \text{.......... (106)}$$

As the volume considered is a unit with curved height s, the area subjected to tractive force should be $\frac{1}{s}$. From Equation (106) the expression of tractive force becomes

$$T = \left(-\frac{w\,V}{g}\frac{dV}{dx} + w\sin\alpha\right)s \qquad \text{.......... (107a)}$$

or,

$$T = w\,(\alpha - \alpha_0)\left[y\frac{\cos\alpha\sin\alpha}{\sin\,(\alpha - \alpha_0)} - \frac{V^2}{g}\right] \qquad \text{.......... (107b)}$$

For uniform flow, $\alpha = \alpha_0$, and

$$\lim_{\alpha=\alpha_0} T = w\,y\cos\alpha\sin\alpha \qquad \text{.......... (108a)}$$

When α is small,

$$T = w\,y\,\alpha \qquad \text{.......... (108b)}$$

For non-uniform flow on a horizontal bottom, $\alpha_0 = 0$, and

$$T = w\,\alpha\left(y\cos\alpha - \frac{V^2}{g}\right) \qquad \text{.......... (109a)}$$

When α is small,

$$T = w\,\alpha\left(y - \frac{V^2}{g}\right) \qquad \text{.......... (109b)}$$

The writer believes that this derivation is more rational than the others previously given. As an arc of equal potential is considered there is no accelerating component in the directions normal to the stream lines. In Fig. 27 one observes that the potential drop of the water surface within the stretch dx, $dx \sin\alpha$, is evidently less than $dx \cos\alpha_0 \tan\alpha$, when two vertical depths $A\,a$ and $B\,b$, instead of two circular arcs $A\,c$ and $B\,d$, are taken for reference. This supports the writer's original assumption that the difference of potential energy between the reach dx is less than that represented by the vertical drop from a to *b.* One can easily note, however, that the derivation is based on certain assumptions, such as:

(1) There is no excessive pressure due to convergence of flow on the arc $B\,d$;
(2) The distribution of static pressure is linear along the arcs.

One can also note that there is a question whether the tractive force should vanish when super-critical velocity occurs in a flume with a horizontal channel bottom. Unless assumptions of this nature could be proved and established definitely, one can scarcely venture to conclude that the foregoing expressions are the correct ones. For the time being, perhaps, it can be presumed that the derivation in the original paper, with due consideration for the convergence of flow, is possibly of the right order for high accelerating flows, whereas the revised expressions are more suitable for cases not much different from parallel flow.

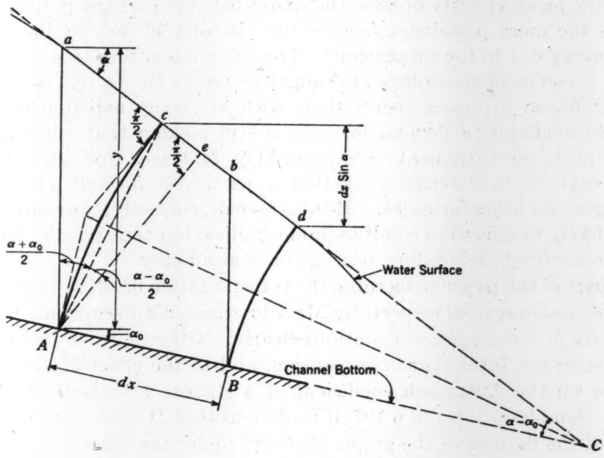

FIG. 27

Professor Lane takes a practical view of the situation pertaining to the bed-load movement in the Mississippi River. Accepting Equation (107*b*) as the correct expression and using Professor Lane's data, it can be shown that there will be motion upward on the sand slopes when the mean velocity of flow does not exceed $\sqrt{g\,y}\sqrt{\dfrac{\cos\alpha\sin\alpha}{\sin(\alpha-\alpha_0)}}$; or, numerically 1.44 ft per sec, above which sediments should move against the direction of flow. This only reveals one of the ambiguities encountered in these latter revisions. Actual records can be found in a report of the Mississippi River Commission.[74] The observation at Bullerton gives: $\alpha_0 = -\dfrac{4.4}{300} = -0.01466$; $\alpha = \dfrac{\alpha_0}{200} = 0.0000733$; $y = 10$ to

---

[74] "The Improvement of the Lower Mississippi River for Flood Control and Navigation"; prepared under the direction of T. H. Jackson, President, Mississippi River Commission, by D. O. Elliott, U. S. Corps of Engineers, Vol. 1, Table XXIII, St. Louis, Mo., 1932.

30 ft; and $V = 3.5$ ft per sec. The report also states[75] that "the quantity of material comprising sand waves was very small as compared with the quantity of material transported in suspension by the river. In the observations on the Fulton Section, Plum Point Reach, it was estimated that the quantity of material composing the sand wave was equal to not more than 2.5% of that carried in suspension."

In discussing sand dune progression the wave action of the water in the vicinity of the dunes should also be considered. A detailed investigation has been reported elsewhere.[76]

Regarding the question as to whether the silt load tends to decrease or increase the mean velocity of flow, the writer believes that the problem will be: Which is the more prominent factor—the viscosity of flow or the change of kinetic energy due to the suspension? The variation of the state of turbulence with the presence of silt in flow also might be one of the factors involved.

Mr. Johnson expresses regret that, with so many experiments and observations available, a general formula is still lacking that will express the quantity of debris movement. Painstakingly, he traces through a method of statical analysis to determine whether a particular formula offers distinct advantages over other formulas. He also reveals, correctly, the sources of error that are likely to affect the result in flume studies; but thus far, the application of these remedies in laboratory testing is not at all easy.

The part of the paper concerning the transportation of silt in suspension has been improved in several respects by Mr. Christiansen's discussion. He defines the validity of the suggested equations clearly. Other parts of the discussion, pertaining to the total load in suspension, and to the effect of silt on kinetic energy or on the Austausch coefficient of a stream, are also helpful. With regard to Samples 6 198 and 6 197, it is obvious that D is assumed equal to D_2, because of the flatness of the grains observed under the microscope.

Referring to Equation (33), the writer wishes to add the following equations so as to facilitate comparison with the other representative expressions reviewed under the heading "Published Authorities." Knowing that $T = 1.609\, w^2\, n^{6/5}\, s^{7/5}\, Q^{6/5}$, it is not difficult to convert Equation (33) into the following approximate form:

$$G = \frac{C\, n^{11/5}}{T_0^{2}}\, s^{7/5}\, Q^{3/5}\, (Q^{3/5} - Q_0^{3/5}) \dots\dots\dots\dots\dots (110)$$

in which $Q_0^{1.2}$ varies as $k_1 \frac{\rho_e\, D_0^{1/3}\, 2\,\beta}{n^{1.2}\, s^{1.4}\, M^{2\beta}}$. When ρ_e, n, and M are constant, and $\beta = \frac{1}{2}$,

$$Q_0^{1.2} = k_2 \frac{\rho_e\, D}{s^{1.4}} \dots\dots\dots\dots\dots\dots (111)$$

in which C, k_1, and k_2 are constants.

In addition to the authorities cited in the paper, the writer wishes to include two more recent publications on debris transportation:

---

[75] "The Improvement of the Lower Mississippi River for Flood Control and Navigation"; prepared under the direction of T. H. Jackson, President, Mississippi River Commission, by D. O. Elliott, U. S. Corps of Engineers, Vol. 1, Table XXIII, St. Louis, Mo., 1932, p. 121.

[76] "Stauraumverlandung und Kolkabwehr," by A. Schoklitsch, Julius Springer, Wien, 1935.

X.—H. J. Casey.—In the summary of his paper,[77] Casey gives two formulas for the rate of transportation, based on experiments with quartz sand (specific gravity, 2.65) with surface slopes ranging from $\frac{1}{400}$ to $\frac{1}{1\,200}$:

$$G = 0.367\, s^{9/8}\, (q - q_0) \qquad \text{(112a)}$$

and

$$G = 0.333\, s\, (q - q_0) \qquad \text{(112b)}$$

in which $q_0 = k \frac{D^{0.75}}{s^{1.25}}$, G and q are units of volume, and k is a constant. Equation (112*a*) is for uniform sand $0.5 \text{ mm} < D < 3.0 \text{ mm}$, whereas Equation (112*b*) is for mixtures.

XI.—A. Shields.—In his paper, Shields[78] attempts to connect the bed-load movement with turbulence and dynamic similarity. He obtains a dimensionless equation of the form:

$$\frac{G}{Q}\left(\frac{\sigma - \rho}{s\,\rho}\right) = 10\,\frac{T - T_0}{(\sigma - \rho)\, w\, D} \qquad \text{(113)}$$

Professor Rouse has discussed this work in some detail.

It may be interesting to demonstrate that there is a critical depth at which the mean load will be a maximum with all other hydraulic factors remaining unchanged. Using Equation (55) and equating to zero, the first differentiation of c_m with respect to d, one finds:

$$\alpha\, d\, e^{\alpha\, d} - e^{\alpha\, d} + 1 = 0 \qquad \text{(114)}$$

This condition could be satisfied only when $d = 0$. Therefore it may be assumed that the shallower the depth the heavier the concentration of silt in suspension will be, provided that other factors beside d remain unchanged.

Observations in the Yungtingho,[79] near Peiping, China, have made it possible to derive two empirical formulas for the total quantity of silt transported in suspension; one in terms of the flow discharge Q:

$$P = a\, Q^{1.54} \qquad \text{(115a)}$$

in which $a = 0.0095$ as an average (its maximum and minimum are, respectively, 0.0363 and 0.0026); and the other in terms of the flow velocity V:

$$P = b\, V^{3.89} \qquad \text{(115b)}$$

in which $b = 2.158$ as an average (its maximum and minimum are, respectively, 45.60 and 0.293). Both Q and V are in metric units and P is expressed as a percentage by weight. By combining Equations (115*a*) and (115*b*) one finds that V varies as $d^{0.656}$, which is not far from that given by Manning's formula.

THE THREE-POINT PROBLEM IN A CO-ORDINATED FIELD

BY R. ROBINSON ROWE,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY OSCAR S. ADAMS, GEORGE D. WHITMORE, JOHN R. JAHN, AND R. ROBINSON ROWE.

SYNOPSIS

An improved method of solving the classical three-point problem, particularly adapted to orientation or location in a previously co-ordinated field, and to calculation by machine instead of by logarithms, is offered in this paper. The probable normal and position errors due to errors of observation are evaluated to measure the precision of the location and, in case more than three points are observed, to aid in the selection of the best three-point set or to weight the adjustment of all sets. A graphical adjustment of the "four-or-more-point" problem is outlined and a practical problem is solved to illustrate the use of the formulas.

THE PROBLEM

In Fig. 1, Points *O*, *A*, *B*, *C*, and *D* are triangulation stations with known co-ordinates in a plane system. If an observer at Point *P* measures the angle, $O\,P\,A = \alpha$, he has limited his position locus to the circle, *O P A*. If he then measures Angle $O\,P\,B = \beta$, he determines his position as the intersection of the circles, *O P A* and *O P B*, unless these two circles coincide. Of course, the circles intersect at two points, but one will be Point *O*; and it can be shown that Angle $A\,P\,B = \beta - \alpha = \theta$ determines a third circle which passes through the intersection at Point *P*. Hence, the observer should measure all three angles and adjust the results before further computation; or he should measure the two angles defining the circles with the best intersection.

If one measures Angles θ and *C P D*, he defines two position-locus circles ordinarily intersecting at two points. His position is fixed if he can decide between them—by a compass bearing, for instance. Such data may give strong locations, but they will be weak if the circles are nearly tangent, or if they are coincident.

NOTE.—Published in June, 1938, *Proceedings*.

[1] Associate Bridge Engr., State Dept. of Public Works, Sacramento, Calif.

With four points, A, B, C, and D, visible, it is best to measure the three angles, θ, $B\,P\,C$, and $C\,P\,D$, and also Angle $A\,P\,D$ for check and adjustment. Then, Angles $A\,P\,C$ and $B\,P\,D$ may be calculated, so that six position-locus circles are defined. Unless all data are exact, there will be four independent points of intersection, due to errors of observation at Point P, errors in the previous co-ordination of the signals, and to the plane projection distortion of the field. If the four intersections are tolerably approximate, considering the probable error of angular measurements, a mean position can be determined by least squares or by the graphical method outlined herein. Otherwise, it may be assumed that at least one of the signals was not accurately located; or, that it has since shifted in position. Such a shift should be anticipated when depending upon old co-ordinates of spires, due to uneven subsidence, translation by earthquake, or altered reconstruction after fires.

If but one signal is in error, a fifth signal can be used to determine which should be rejected. Then, a complete set would determine ten circles and ten independent intersections. A graph of these intersections would show four points tolerably approximate, the other six being erratic and dependent upon the signal which must be rejected.

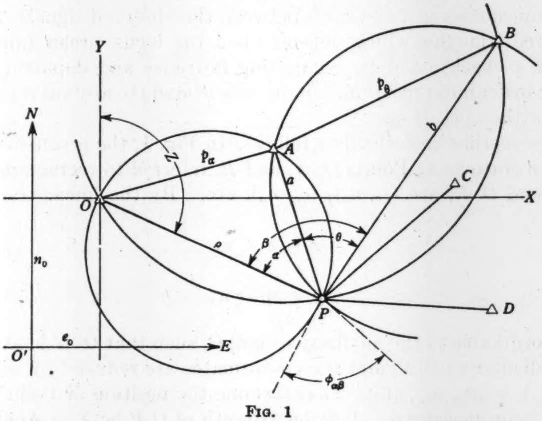

FIG. 1

Use of six or more signals increases the labor of solution, but there is the possibility that more than one station must be rejected or that some locus circles will intersect at very acute angles, too small for the desired precision. The field data to all visible signals should be obtained. In general, for observations on n signals, the number of locus circles, N_c, is:

$$N_c = 0.5\,n\,(n-1) \qquad (1)$$

and the number of independent intersections, N_i, is:

$$N_i = \frac{n!}{6\,(n-3)!} \qquad (2)$$

Along the coasts, many areas have been co-ordinated by the United States Coast and Geodetic Survey and the United States Engineer Office. Re-establishment of the instrument points is not always simple, but co-ordinated spires are usually abundant. The three-point method affords a practical device for: (1) Connecting to the U. S. Coast and Geodetic horizontal datum (plane and geographical co-ordinates); (2) determining azimuth without astronomical observations, particularly when the sun or the stars are obscured, or when they are not in favorable position; or (3) controlling a stub traverse by three-point ties near each end, which, incidentally, serves to check base lines or rate the tape used in the traverse. The solutions of connections required in a resurvey of a part of the mean high-tide line of Coronado, South Island, California, in 1929, led to the development of the methods described in this paper.

SOLUTIONS

The graphical solution on the plane-table is known to all topographers and is explained in most surveying texts. The methods in this paper are not applicable to such work. The usual trigonometric solution requires: (*a*) Computing closing courses and distances between the observed signals; (*b*) solving a series of three triangles which depend upon the locus circles (and two more triangles for a check); and (*c*) computing latitudes and departures from one signal to the instrument position. Reference is made to any surveying textbook for details of the operations.

A simpler method is derived as follows: In Fig. 1, the given co-ordinates of triangulation stations at Points O, A, and B, referred to rectangular Cartesian axes, $O'\,N$ and $O'\,E$, are (e_o, n_o), (e_a, n_a), etc. By the linear transformation, the formulas,

$$x = e - e_o \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

and,

$$y = n - n_o \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

refer all co-ordinates to the auxiliary origin, O, such that $O'\,N$ is parallel to $O\,Y$ and perpendicular to $O\,X$, and the co-ordinates are reduced by subtraction to $O = (0, 0)$, $A = (x_a, y_a)$, etc. To determine the position of Point P, Angles α and β have been measured. Let the azimuth of $O\,P$ be Z = Angle $Y\,O\,P$.

Determining the equations of Lines $O\,P$, $A\,P$, and $B\,P$, Fig. 1, from slope forms, and remembering that $\tan (A - B) = \dfrac{\tan A - \tan B}{1 + \tan A \tan B}$,

Line $O\,P$:

$$\frac{y}{x} = \frac{y_p}{x_p} = \cot Z \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4a)$$

Line $A\,P$:

$$\frac{y - y_a}{x - x_a} = \frac{y_p - x_p \tan \alpha}{x_p + y_p \tan \alpha} \quad\ldots\ldots\ldots\ldots\ldots (4b)$$

and, Line $B\,P$:

$$\frac{y - y_b}{x - x_b} = \frac{y_p - x_p \tan \beta}{x_p + y_p \tan \beta} \quad\ldots\ldots\ldots\ldots\ldots (4c)$$

and, these lines being concurrent at Point P, simultaneous solution of their equations will determine the position of P. Substituting Equation (4*a*) in

Equations (4b) and (4c) to eliminate x_p and y_p, then:

$$(x^2 + y^2)\tan\alpha = x\,(x_a\tan\alpha + y_a) + y\,(y_a\tan\alpha - x_a)\ldots\ldots(5a)$$

and,

$$(x^2 + y^2)\tan\beta = x\,(x_b\tan\beta + y_b) + y\,(y_b\tan\beta - x_b)\ldots\ldots(5b)$$

Dividing Equation (5a) by Equation (5b) and simplifying:

$$\frac{y}{x} = \frac{(x_b - x_a)\tan\alpha\tan\beta + y_b\tan\alpha - y_a\tan\beta}{(y_a - y_b)\tan\alpha\tan\beta + x_b\tan\alpha - x_a\tan\beta}\ldots\ldots\ldots(6)$$

Dividing the third and fourth parts by $\tan\alpha\tan\beta$ and substituting Equation (4a):

$$\cot Z = \frac{x_a - x_b + y_a\cot\alpha - y_b\cot\beta}{-\,y_a + y_b + x_a\cot\alpha - x_b\cot\beta}\ldots\ldots\ldots\ldots(7)$$

At Point P in Equation (5a), $x = x_p$; $y = y_p$; $x^2 + y^2 = x^2\csc^2 Z$; and, $y = x\cot Z$. Substituting these values in Equation (7):

$$x_p^2\csc^2 Z\tan\alpha = x_p\,(x_a\tan\alpha + y_a) + x_p\cot Z\,(y_a\tan\alpha - x_a)\ldots(8a)$$

$$x_p = \sin^2 Z\,[x_a + y_a\cot\alpha + \cot Z\,(y_a - x_a\cot\alpha)]\ldots\ldots\ldots(8b)$$

$$y_p = \cos^2 Z\,[\tan Z\,(x_a + y_a\cot\alpha) + y_a - x_a\cot\alpha]\ldots\ldots\ldots(8c)$$

and,

$$l = O\,P = \sin Z\,(x_a + y_a\cot\alpha) + \cos Z\,(y_a - x_a\cot\alpha)\ldots\ldots(8d)$$

For the most direct solution, solve Equation (7) for Z; then Equation (8b) for x_p; and then:

$$y_p = x_p\cot Z\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(9)$$

If Z is not required, solve Equation (7) for $\cot Z$; and, for Equation (8b), use

$$x_p = \frac{1}{1 + \cot^2 Z}\,[x_a + y_a\cot\alpha + \cot Z\,(y_a - x_a\cot\alpha)]\ldots\ldots(10)$$

In Equation (7) there will be two solutions for Z differing by 180°; but if the wrong Z is selected, then l from Equation (8d) will be negative and the same point will be determined by either choice of Z. The other equations are free from ambiguity except in singular cases. In the insoluble case with O, A, B, and P lying on a circle, Equation (7) gives $\cot Z = \frac{0}{0}$. If $\alpha = 0°$ or $180°$, $\cot Z = \frac{\infty}{\infty}$, the apparent indeterminacy having been introduced by the division by $\tan\alpha\tan\beta$ $(= 0)$. This case is best solved by a simple resection triangle; or, determining Equation (7) by limits:

$$\cot Z = \frac{y_a}{x_a}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(11)$$

and, substituting Equation (11) in Equation (5b),

$$x_p = \frac{x_a}{x_a^2 + y_a^2}\,[x_a\,x_b + y_a\,y_b + \cot\beta\,(x_a\,y_b - x_b\,y_a)]\ldots\ldots(12)$$

To complete the solution, co-ordinates to the origin, O', can be computed by reversing the transformation of Equations (3) by:

$$e_p = x_p + e_o \tag{13a}$$

and,

$$n_p = y_p + n_o \tag{13b}$$

If true azimuth is desired, Z must be corrected for the difference in longitude represented by the distance, e_p.

Relative Weights and Figure Strengths

In Fig. 1, with Angle θ observed between given Signals A and B, the equation of Circle $P\ A\ B$ is:

$$\begin{aligned} x^2 + y^2 - x\left[x_b + x_a + (y_b - y_a) \cot \theta\right] - y\left[y_b + y_a - (x_b - x_a) \cot \theta\right] \\ + x_b\, x_a + y_b\, y_a + (x_a\, y_b - x_b\, y_a) \cot \theta = 0 \end{aligned} \tag{14}$$

The tangent to this circle at Point P is:

$$\begin{aligned} & x\left[2\, x_p - x_a - x_b + (y_a - y_b) \cot \theta\right] \\ & \quad + y\left[2\, y_p - y_a - y_b - (x_a - x_b) \cot \theta\right] + 2\, x_a\, x_b \\ & \quad + 2\, y_a\, y_b - x_p\, (x_a + x_b) - y_p\, (y_a + y_b) \\ & \quad + \cot \theta\left[2\, x_a\, y_b - 2\, x_b\, y_a + x_p\, (y_a - y_b) - y_p\, (x_a - x_b)\right] = 0 \end{aligned} \tag{15}$$

The slope of the circle and tangent at Point P is:

$$\lambda_{p(ABP)} = - \frac{2\, x_p - x_a - x_b + (y_a - y_b) \cot \theta}{2\, y_p - y_a - y_b - (x_a - x_b) \cot \theta} \tag{16a}$$

and the slope for Circle $O\ A\ P$, substituting α for θ and $x_b = y_b = 0$:

$$\lambda_{p(OAP)} = - \frac{2\, x_p - x_a - y_a \cot \alpha}{2\, y_p - y_a + x_a \cot \alpha} \tag{16b}$$

In the general triangle, $A\ B\ P$, let the three angles be A, B, and θ, and let the opposite sides be b, a, and p_θ, respectively. If there was a small error, $\Delta\theta$, in the measurement of θ there will be little change in the slope from Equation (16a). Practically, the tangent is in error by a normal distance, ΔN, such that:

$$\begin{aligned} \Delta N &= \tfrac{1}{2}\, p_\theta \left[\Delta\, (\csc \theta) + \Delta\, (\cot \theta) \cos\, (A - B)\right] \\ &= - \frac{p_\theta\, \Delta\theta}{2 \sin^2 \theta} \left[\cos \theta + \cos\, (A - B)\right] \\ &= - p_\theta\, \Delta\theta\, \frac{\sin A \sin B}{\sin^2 \theta} = - \Delta\theta\, \frac{ab}{p_\theta} \end{aligned} \tag{17}$$

If the error in seconds of arc is expressed by δ'', and N is the absolute normal error:

$$N_\theta = \frac{(\delta'')\, a\, b}{206\,265\, p_\theta} \tag{18}$$

In the use of Equation (18) in the solution of four-or-more-point systems, it is necessary to solve for N only to two or three significant figures. Having approximated P from one set of three points and λ for any pair of those points, a, b, and p can be scaled; δ'' can be determined as the probable error of that measurement; and, N can be computed. Now, the angle, $\theta \pm \delta''$, has limited the locus for P to a band of width, $2\ N$, slope, λ, centered on Point P, since a short part of the locus circle is essentially a straight line. Intersection of this band with bands pertinent to other combinations of points should further limit this locus area. If probable errors for all sets are then gradually reduced in the same ratio until only one point is common to all bands, there will result an acceptable solution which will generally be very close to the least squares solution. The reduction can be done rapidly by cut-and-try on a large-scale graph.

If the bands do not have a common area, at least one error will exceed the computed probable error. To obtain a solution, gradually increase the widths of all bands in the same ratio until there is just one point common to all. In either case, the common point will be the intersection of the edges of three bands. If two of these critical bands are nearly parallel, the solution can usually be improved by letting these two nearly parallel band edges determine their median as a line locus; then the width of all other bands can be decreased gradually in proportion to their normal errors until the common area of these remaining bands has only one point on the determined line locus. This adjustment will have increased the departure from the nearly parallel bands by a small amount, but will have decreased the departure from most of the other bands by a relatively large amount.

Equation (18) can be used reciprocally for weighting a series of angles observed in a four-or-more-point system. The relative strength of different such figures is found by holding δ'' constant; and, since constants are unnecessary in strength comparison, the relative figure strength may be expressed as:

$$s_\theta = \frac{p_\theta}{a\,b} \quad \text{(19)}$$

To obtain the absolute position error from a three-point observation with only two angles measured (such as Angles α and θ) compute N_α and N_θ from Equation (18), measure or compute $\phi_{\alpha\theta}$, the acute angle between slope tangents, $\lambda_{p(OPA)}$ and $\lambda_{p(APB)}$, from Equation (16a) or Equation (16b). Then, the absolute position error, $\Delta_{\alpha\theta}$, is the long semi-diagonal of a parallelogram with one angle, $\phi_{\alpha\theta}$, and altitudes, N_α and N_θ; or,

$$\Delta_{\alpha\theta} = \csc \phi_{\alpha\theta} \sqrt{N_\alpha{}^2 + N_\theta{}^2 + 2\ N_\alpha\ N_\theta \cos \phi_{\alpha\theta}} \quad \text{(20a)}$$

and, reciprocally, the relative strength of the three-point figure compared to others is:

$$S_{\alpha\theta} = \frac{p_\alpha\ p_\theta \sin \phi_{\alpha\theta}}{a\ \sqrt{l^2\ p_\theta{}^2 + 2\ b\ l\ p_\alpha\ p_\theta \cos \phi_{\alpha\theta} + b^2\ p_\alpha{}^2}} \quad \text{(20b)}$$

If all three angles, α, β, and θ, were measured, the probable errors of each observation are interdependent and there would be three solutions for Equations (20). If the angles and probable error are balanced, the three normal-error bands will intersect with a hexaparallelogram for a common area, and the position error is the greatest of the three semi-diameters,

$$\Delta_{\alpha\beta\theta} \underset{>}{\equiv} N_\theta \csc \theta_{\beta\theta} \qquad \text{(21}a\text{)}$$

or, $N_\alpha \csc \phi_{\alpha\beta}$, etc. Reciprocally, the relative strength of the three-point figure with all three angles measured, is,

$$S_{\alpha\beta\theta} \underset{<}{\equiv} S_\alpha \sin \phi_{\alpha\theta} \text{ (etc.)} \qquad \text{(21}b\text{)}$$

EXAMPLE

Fig. 2 shows positions of seven spires observed from Point *P*, which was taken arbitrarily on the roof of the Guymon Building, in San Diego, Calif.

FIG. 2.—LOCATION OF PROBLEM STATIONS, SAN DIEGO COUNTY, CALIFORNIA

Plane co-ordinates were taken from the "Map of San Diego Harbor, Calif., Harbor Lines," of the U. S. Engineer Office, dated September 24, 1927, which data had been computed from the U. S. Coast and Geodetic Survey's triangulation of many years before. Angles were turned with an engineer's transit equipped with a 30″ vernier. To illustrate the method of weighting, repetitions were purposely varied in the range from 4 to 20. The basic data and the transformation of Equation (3*a*) are given in Table 1.

TABLE 1.—BASIC DATA AND SOLUTION OF EQUATION (3*a*)

A first approximation, p_1, is computed from the three-point Triangle $O\,D\,E$, and Equations (7), (8*b*), and (9):

Given: x_d, y_d, x_e, y_e, α, and β, from Table 1

$\alpha = 119° 18' 17''$; $\cot\alpha = -0.5612822$

$\beta = 256° 43' 00''$; $\cot\beta = +0.2360829$

$x_d =$	+ 3 996.9	
$y_d \cot\alpha =$	− 7 309.52	− 3 312.62
$-x_e =$		−10 758.7
$-y_e \cot\beta$		− 2 515.82
numerator		−16 587.14
$-y_d$	−13 022.9	
$x_d \cot\alpha$	− 2 243.39	−15 266.29
y_e		+10 656.5
$-x_e \cot\beta$		− 2 539.95
denominator		− 7 149.74

$$\cot Z = \frac{-16\,587.14}{-\ 7\,149.74} = +2.3199641$$

$Z = 203° 19' 04.9''$

$\sin Z = -0.3958345$

$$x_p = (-0.3958345)^2\,(-3\,312.62 + 2.3199641 \times 15\,266.29) = +5\,030.31$$

$$y_p = 2.3199641 \times 5\,030.31 = +11\,670.14$$

The foregoing outline would complete the solution if no other signals had been observed, and Equation (13*a*) would give P = East 7 499.81, South 13 971.36. From Equation (16*a*), $\lambda_{p(ODP)} = -\dfrac{2 \times 5\,030.31 + 3\,312.62}{2 \times 11\,670.14 + (-15\,266.29)} = -1.6563$; and, similarly, $\lambda_{p(OEP)} = +0.211$; and, $\lambda_{p(DEP)} = -0.945$. From field data not given, the probable angular errors were computed to be: $\delta_\alpha'' = 4.7$; $\delta_\beta'' = 5.9$; and $\delta_\theta'' = 7.6$. By scaling Fig. 2, $l = 12\,700$; $P\,D = 1\,700$; $P\,E = 5\,800$; and $O\,D = 13\,600$. Then, from Equations (18) and (19): $N_\alpha = \dfrac{4.7 \times 12\,700 \times 1\,700}{206\,265 \times 13\,600} = 0.036$ ft. Similarly, $N_\beta = 0.142$; $N_\theta = 0.051$; $S_\alpha = \dfrac{13\,600}{12\,700 \times 1\,700} = 0.00063$; $S_\beta = 0.00020$; and $S_\theta = 0.00071$. Hence, in this three-point set, Triangle $P\,D\,E$ is the strongest figure, but the greater accuracy used in measuring the angle in Triangle $P\,O\,D$ gives the latter a greater weight.

The angles between slope tangents were measured by protractor as $\phi_{\alpha\beta} = 70.8°$; $\phi_{\alpha\theta} = 15.5°$, and $\phi_{\beta\theta} = 55.3°$. From Equation (20*a*),

$$\Delta_{\alpha\beta} = \csc 70.8° \sqrt{0.036^2 + 0.142^2 + 2 \times 0.036 \times 0.142 \cos 70.8°} = 0.177$$

and, similarly, $\Delta_{\alpha\theta} = 0.322$; and, $\Delta_{\beta\theta} = 0.220$. Hence, if only two of the three angles are to be measured, α and β would give the greatest accuracy. With all three angles measured, the position error is reduced to $\Delta_{\alpha\beta\theta} = 0.142 \csc 70.8° = 0.151$. For comparison with other three-point sets, the relative strength of the figure is $S_{\alpha\beta\theta} = 0.00063 \sin 15.5° = 0.000166$.

In routine calculations, the experienced computer will usually be able to select the strongest figures by eye. It may be of interest, however, to compare calculated strengths for the great variety of figures shown in Fig. 2. With calculations similar to the foregoing, using a slide-rule or a graph where less than four significant figures are carried, the data in Table 2 were obtained for the 21 position-locus circles. Note that two distant points (such as Points *A* and *C*) give low precision, but that either one combined with a near point gives great precision.

TABLE 2.—RELATIVE VALUES OF COMPUTED STRENGTH

Signals	Probable error, in seconds of arc	Slope	Normal error for 1″	Probable normal error	Strength, $10^5 S$
(1)	(2)	(3)	(4)	(5)	(6)
O A	2.6	+50.45	0.090	0.23	5.4

D E F	9.44	71.01	19.2	74.2	86.6	0.15	23.0

(note *O A F*, *O C F*, *A B E*, and *B D F*); (*c*) because of the large position error in Column (7), Table 3, or the low figure strength in Column (8); or, (*d*) because of any combination of Causes (*a*), (*b*), and (*c*). If all angles are measured to nearly the same precision, figure strength is the easiest determinant; but if field precisions were quite varied, position error is a better comparison. First, however, one must determine the position more closely from the more precise sets (say, *O D E*, *B D E*, and *D E F*, giving a mean of E. 7 499.62, S. 13 971.18) and list any intersections that fall much farther from this position than their calculated position errors. In this example, all intersections seem tolerable except for twelve of the fifteen that are dependent upon Signal *O*, which is sufficient evidence for the rejection of all data depending upon *O*. A study of the large-scale plot of these intersections makes the conclusion more obvious.

Eliminating these intersections and four others that have probable position errors greater than 3 ft, the other sixteen intersections are plotted to a large scale in Fig. 3. Bands the width of the probable normal error on each side of the lines do not intersect with an area common to all. Increasing each band width by 45%, a common point, P_1, is found on the edges of bands of *B F*, *B D*, and *A B*, and within all other bands. As *B D* and *B F* are nearly parallel, draw the median to the edges of those bands. By diminishing the width of all other bands until the width of each side is 2% greater than the probable error, the diminished common area just touches the median at P_2. This point is accepted as the solution; its departure from position-locus circles is about 1.50 times the probable error for two circles; 1.02 times for two others; and, less than the probable error for the other twelve. The least squares solution, which is too long for inclusion herein, gives Point *Q*, distant 0.03 ft from Point P_2 and has a probable error of 0.13 ft.

FIG. 3.—GRAPHICAL SOLUTION OF A SIX-POINT SET

Before concluding, the rejected signal, O, must be disposed of. Computing closing azimuths from P_2 to each of the other signals, and then Azimuth $P_2 O$ from these and the measured angles, the resulting six values may be expressed as 203° 19′ 13″.5 ± 4″.2, with a weighted mean of 203° 19′ 13″.7. The closing azimuth from P_2 to the given position of O is 203° 18′ 58″.9. The difference, 14″.8, is the angle subtended at P_2 by the position error of O. As the distance is about 12 708 ft, the normal projection of this position error is 0.92 ft. Measurement of the position-error projection from another instrument point would determine the absolute error, and, thereafter, the station could be used.

It should not be concluded that the other six signals have been proved correct. Any of them might have had a shift in such a direction that its normal projection from P is small; or a distant signal might have an error that would not be appreciable until the survey approached it.

Summary and Conclusions

The salient features of the paper may be summarized as follows:

(1) The three-point problem may be solved by formulas, without ambiguity;

(2) The use of spires, co-ordinated by responsible surveys, affords a simple method of connecting to other systems or controlling spur traverses;

(3) If such spires have not been observed recently, shifts due to several causes should be anticipated (use of a fourth spire affords a check; and, a fifth spire will serve to eliminate one which is in error);

(4) Methods of analysis of four-or-more-point systems have been outlined fully (the experienced computer may substitute his judgment for formulas expressing relative strengths of figures); and,

(5) The graphical method of compromising intersection errors by representing each line by a band of width proportional to its probable error is also applicable to ordinary triangulation, particularly in the convergence of second-order surveys to locate third-order stations.

Acknowledgments

The formulas were developed while the writer was associated with Tom J. Allen, Assoc. M. Am. Soc. C. E., and appreciation is expressed for his co-operation. The field observations for the illustrative example were made by Eric V. A. Quartly, Assoc. M. Am. Soc. C. E.

DISCUSSION

Oscar S. Adams,[2] **Esq.** (by letter).—Many papers dealing with the three-point problem can be found in periodicals devoted to engineering and surveying. Any treatment of the subject by means of co-ordinates must necessarily depend upon the same principles. The paper by Mr. Rowe is developed in a very complete manner and it should be useful to any surveyor who may wish to take advantage of this method of connection to control.

The U. S. Coast and Geodetic Survey is following the practice of computing the plane co-ordinates of all the triangulation stations on the State plane-co-ordinate systems. In the end every station will have its plane co-ordinates given as well as its geodetic position. For some States this work is already practically completed and, in course of time, this will be true of all the States. In any region that lies near the various arcs of triangulation, tanks, steeples, and other such objects, are located by intersection observations. This work should form a good basis for the application of the three-point fix.

Besides the work of the Coast and Geodetic Survey, the U. S. Geological Survey, the Corps of Engineers of the U. S. Army, and other surveying and engineering organizations have located many prominent objects in the vicinity of their operations. All these stations can be used indiscriminately if they are all computed on the same basis and are mutually dependent for their datum. Of course if they are not so co-ordinated, each would have to be used independently of the others. The Coast and Geodetic Survey developed the State plane-co-ordinate systems with the hope that all other organizations would make use of them in their work and that all work would be tied to the control net of the country. If this hope should be realized, all work of the various organizations would be on a common basis, and all results would have a permanent value for any succeeding work. If this could be accomplished there would be a great mass of data available for use in many regions where now there is great lack of such control.

The three-point fix has a practical and valuable use in hydrographic surveying, in determining locations offshore, and in plane-table work in topographic mapping. A three-point location, however, even when dependent on accurately located stations, is not of sufficient accuracy to justify its use in the extension of control, except for surveys of the lower order. The use of intersection stations is not advocated as the basis of control for second-order surveys and little dependence can be placed, as far as control is concerned, on a three-point location which is based upon tanks, steeples, water towers, or intersection stations of any kind.

In army operations in time of war, much use is made of this method of determining positions. The Allied Armies in France had a method of computation for the three-point fix dependent upon the grid system in use in the World War Zone. This method, of course, depended upon plane co-ordinates.

The author is to be congratulated upon the excellence of his development of the computation formulas. The treatment is logical and the resulting formulas would be easy of computation with an ordinary calculating machine. The discussion of the accuracy of the results is very well done. As a final word, it is desired to repeat the warning against the use of this method where any accuracy of location is essential. As already stated, it has its use—and an important use—but as control for further work, it is not to be employed even under the most favorable circumstances.

---

[2] Senior Mathematician, U. S. Coast and Geodetic Survey, Washington, D. C.

George D. Whitmore,[3] M. Am. Soc. C. E. (by letter).—As shown by the author, three-point triangulation has a definite place in modern surveying and mapping practice. For its successful use, however, its peculiar characteristics and limitations must be recognized. For example, it may be said that, in general, a horizontal position established by three-point triangulation (resection) is never as strong as the position established from the same basic control stations by "cuts" (intersection). Furthermore, it is true that there are many instances in which the position from a three-point determination might be uncertain or even unsolvable, whereas the same position might be strong if the intersection method of "cuts" were used. In many cases, the strength or weakness of a three-point location is not immediately apparent to the field man, this being a rather serious disadvantage if the basic control stations are scarce and if advance planning of the field work is not practicable.

Three-point triangulation can often be used to advantage, however, under the following conditions, if too high an order of accuracy is not required:

(1) When it is not practicable to occupy the basic control stations (for example, if the basic control includes a large percentage of spires, cupolas, stacks, towers, etc., impossible to occupy with an instrument for "cut-in" work without an expensive building for instrument support);

(2) When the basic control is already signaled (in this case, under the three-point method, no new construction would be required except for instrument supports at the three-point stations);

(3) When the ratio of new supplemental stations to existing basic stations is high (obviously, it would be cheaper to construct a few signals at the existing basic stations for three-point observations than to construct many signals at the new supplemental stations for "cut-in" observations); and,

(4) When flexibility in the observing schedule is required.

During the two years, 1937–1938, in connection with a topographic mapping project in the Tennessee Valley, more than 700 three-point stations have been established as detailed horizontal control. The terrain being mapped under this program includes several thousand square miles in the Appalachian Mountains of Eastern Tennessee and Western North Carolina, and is generally heavily wooded and quite inaccessible. There are many peaks with elevations that exceed 5 000 ft, the floors of the valleys averaging about 1 200 ft. The basic control already in existence consists of the first-order and second-order triangulation of the U. S. Coast and Geodetic Survey, with about one station to each 50 sq miles; and third-order triangulation of the U. S. Geological Survey, with an average of one station for each 12 sq miles. It is necessary to supplement this basic control with additional stations averaging about one for each 4 sq miles. Three-point triangulation is the principal method used to establish this supplemental control.

---

[3] Chf. of Surveys, Maps and Surveys Div., TVA, Chattanooga, Tenn.

The mapping of this area is by the stereo-topographic process, using aerial photographs. Because of the characteristics of this method, the supplemental control stations must be established in certain restricted locations, namely, in the common overlap areas of several photographs, and close to some definite point which can be identified on all the overlapping photographs. Thus, there is very little latitude in selecting the locations of these supplemental control stations. Furthermore, the observing schedule is such that it is not practical to "cut in" all supplemental stations with one visit to each basic control station. If the "cut in" method were used, many return visits to these basic control points would be required. Under the three-point method, only one trip is made to each basic control station, at which time specially designed pyramid signals are erected, and precise vertical angles measured for the determination of elevations on these basic stations.

In order to meet the accuracy required by the maps, the horizontal position of each supplemental control station must be correct to within 10 ft in relation to the basic control, the horizontal plotting scale of the map being either 1 : 10 000 or 1 : 15 840. To obtain this fourth-order accuracy in the three-point locations, repeating theodolites are used, equipped with verniers reading to 0° 0′ 20″. Six repetitions direct and reverse are taken on each angle, including the angle closing the horizon. The lengths of the sights occasionally run as high as 10 miles, and average 4 to 5 miles. Usually four or more basic control stations are visible from each three-point station, all near-by visible basic stations being observed, of course.

Early in this program the advantages of making all computations and adjustments of three-point stations in a co-ordinated field were recognized. The State-wide plane co-ordinate systems originated by the Coast and Geodetic Survey were adopted as the computing medium. It is interesting to note that the formulas developed by the computing staff for the solution of the three-point locations are substantially the same as those developed by the author. A simple and "fool-proof" computation form, based on Equation (10), has been in use for some time. The angular value of Z is obtained by an inverse solution as a part of the routine check on the work. The research in developing these computing and adjusting methods was done principally by W. O. Byrd, Assistant Mathematician, working under the close direction of C. C. Miner, Assoc. M. Am. Soc. C. E., head of the Surveys Computing Staff of the Tennessee Valley Authority.

The formulas developed by the author to determine the "relative weight and figure strengths" are very useful and have an important application. For the successful utilization of three-point triangulation, it is absolutely necessary to avoid weak figures. The Surveys Computing Staff has made extensive use of this principle, not so much in the refined adjustment of the three-point figures, as in selecting the strongest figure from which to establish each three-point position.

The experiences of this same organization indicate that a refined or delicate adjustment of a three-point position is not justified unless the basic control is of a high order of accuracy, and located so as to provide several reasonably strong figures for each three-point location. When these conditions do not exist, the method used has been to select the strongest figure and base the determinations entirely upon that figure. The remaining pointings are then used as checks on the work. These checks are made rapidly and consist of comparing the observed directions with the computed directions.

Occasionally, it has been found desirable to determine the most probable value of a three-point position by taking advantage of all observations to all basic stations. The least squares method of adjustment,[4] is very satisfactory and can possibly be made in less time than the "cut-and-try" method advanced by the author. An experienced computer can complete such an adjustment with pointings on five stations in less than 2 hr.

The method of establishing elevations at three-point stations in connection with the topographic mapping project may also be of interest. Elevations are required to be correct to within 4 ft, with respect to the nearest basic vertical control, the contour interval being 40 ft, with half-interval, 20-ft contours being shown in all flat and critical areas. Elevations are first established on the basic control stations, either by spirit leveling, or by vertical angles of a high degree of precision. To determine the elevation of a three-point station vertical angles to each of the visible basic control stations are read, the measurement consisting of two readings with telescope direct and two readings with telescope reversed, using a vertical circle reading to 0° 0′ 20″. Then, utilizing the horizontal lengths computed from the three-point problem, the observed vertical angles, and a field-determined coefficient of refraction, the difference of elevation between the three-point station and each basic control station observed upon is computed. Each basic control station observed thus furnishes an elevation for the three-point station, the final elevation of the new station usually being the mean of the elevations from the various basic stations.

John R. Jahn,[5] **Esq.** (by letter).—In bringing this valuable graphical device into a more exact form for use in balanced surveys, the author is to be congratulated. His method is ingenious and should be of considerable value in the work of the larger surveying organizations that employ men who are sufficiently skilled in the mathematics of geodesy so that errors of manipulating the formulas, and errors of technique in the analysis, do not defeat the straightforward solution of the problems. In the illustrative example, the basic data, with the exception of that applying to Station *O*, are of uniformly high accuracy. Had this not been the case, the analysis would probably have failed, due to ambiguity in the many sets of possible locations for Station *P*. The writer has spent much time attempting to find single points that would satisfy the directional data for more than three-point groups. Part of the trouble was caused by slightly inaccurate angular data and part by slightly inaccurate station positioning. The author's method of working toward the most reasonable position by the use of unit bands was attempted without success, although the finer analysis that Mr. Rowe uses was not then known to the writer.

---

[4] *Special Bulletin No. 138,* U. S. Coast and Geodetic Survey, p. 114.

[5] Civ. Engr., Riverside, Calif.

In the example, the observed angles were adjusted to seconds. This indicates the use of an instrument more accurate than the ordinary engineer's transit, reading to minutes. Multiple pointings can be taken and the average value used. However, to be of use to the average trained surveyor, the writer believes that a simpler method of analysis is necessary to enable the surveyor to add this "three-point problem" to his mental equipment. For several years, the writer has been attempting to formulate a procedure, using the mathematics of analytic geometry in co-ordinated field data, in order that field survey points might be referenced to established landmarks, such as flag-poles, steeples, windmills, etc., whose "positions" could be determined closely. This is particularly valuable in open country, where near-by reference points are not always at hand. With a transit line tied into co-ordinated landmarks by three-point or multiple-point directional data, the recovery of old stations would be considerably aided.

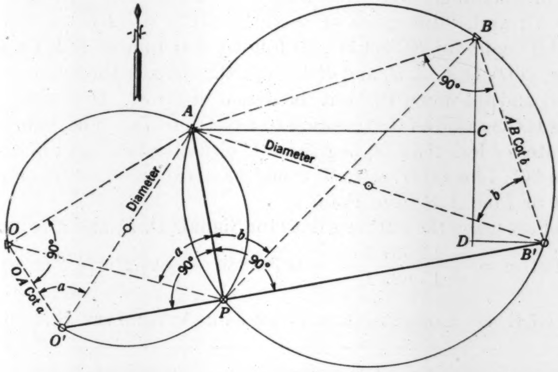

FIG. 4

In Fig. 4 which is similar to Fig. 1, Point P lies at the intersection of the two determining circles passing through Points O and A and through Points A and B. By constructing Point O' such that $\overline{OO'} = \overline{OA} \cot a$, Circle $O\,A\,P$ is divided by Diameter $A\,O'$, since $O'\,O\,A$ is a right angle and Chord $O\,A$ subtends Angle a; hence, Angle $A\,P\,O'$ is a right angle. By like construction $\overline{BB'} = \overline{AB} \cot b$, and likewise Angle $A\,P\,B'$, is a right angle. Hence, $O'\,PB'$ is a straight line and Point P is located at the intersection of two lines, one through Points O' and B', the "closing line" of a traverse having a slope,

$$m = \frac{dy}{dx} = \frac{\text{Difference of northings}}{\text{Difference of eastings}} \quad \ldots\ldots\ldots\ldots\ldots (22)$$

and the other through Point A and having a slope at right angles to the former.

If Line $O' B'$ is expressed by the equation,

$$y = m\,x + c_B \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(23a)}$$

and the line through Point A is expressed by the equation,

$$x = -\,m\,y + c_A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(23b)}$$

the two equations may be solved for x_P and y_P from the combination; that is, $x_P = -\,m^2\,x_P - m\,c_B + c_A$, or,

$$x_P = \frac{-\,m\,c_B + c_A}{1 + m^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(24)}$$

This would be laborious if the lengths of Lines $O\,A$ and $A\,B$ were to be computed as the square root of the sum of the squares of co-ordinate differences. However, Triangles $A\,C\,B$ and $B\,D\,B'$, representing the longitude and latitude differences of Lines $A\,B$ and $B\,B'$, are similar to each other since corresponding angles are equal. Then, $\frac{\overline{AC}}{\overline{BD}} = \frac{\overline{BC}}{\overline{DB'}} = \frac{\overline{AB}}{\overline{BB'}}$; but $\overline{BB'} = \overline{AB} \cot b$, so that "difference of northings, $\overline{BB'}$" (or BD) = "difference of eastings, $\overline{AB}$" $\cot b$ (or $\overline{AC} \cot b$); and, "difference of eastings, $\overline{BB'}$" (or $\overline{DB'}$) = "difference of northings, $\overline{AB}$" $\cot b$ (or $\overline{BC} \cot b$). It follows that Line $O'\,B'$ is the closing line of a traverse, $O\,O'$, $O\,A$, $A\,B$, and $B\,B'$, and the signs of the several courses can be visualized and set down without likelihood of error. It is to be noted that this analysis is the same as that leading to Equation (7). Fig. 4 shows Angles a and b as acute, or less than 90 degrees. If either or both had been obtuse, or greater than 90°, Lines $O\,O'$ or $B\,B'$ would have extended on the opposite sides of Line $O\,A$ or Line $A\,B$ from Point P.

A work sheet using the author's data for Signals D, E, and F is illustrated by Table 4. Let $m = \frac{-\,11\,991.9}{-\,15\,699.1} = +\,0.763859 = \cot 52° \, 37\tfrac{1}{2}'$; from which the

TABLE 4.—Computation Form for Alternate Solution

Signal (See Fig. 2)	Azimuth	Included angle	Differences of:		Co-ordinates		Remarks
			Northings	Eastings	North	East	
F′.....	....				....	....	Not required
		....	−413.3*	+5 837.8			
F.....	194° 24′.5				−20 033.7	+5 941.4	Given
		128° 12′.75	+7 415.1	+525.0			
D.....	322° 37′.25				−12 618.6	+6 466.4	Given
		137° 24′.75	−2 366.4	+6 761.8			
E.....	100° 02′				−14 985.0	+13 228.2	Given
		....	+7 356.5	+2 574.5			
E′.....					−7 628.5	+15 802.7	From Signal *E*
....	....	....	−11 991.9	−15 699.1	....	....	To balance

* 413.3 = 525 × cot 128° 12$\tfrac{3}{4}$′.

true bearing of Line $D\,P$ is $270° + 52° \, 37\tfrac{1}{2}' = 322° \, 37\tfrac{1}{2}'$ (as read, $322° \, 37\tfrac{1}{4}'$; and, therefore, the correction to the angles is $+\,\tfrac{1}{4}'$).

At Point E', Equation (23a), for Line $E'\,F'$, yields: $y = +\,0.763859\,x - 19\,699.5$ ($c_{B'} = -\,15\,802.7 \times 0.763859 - 7\,628.5$).

At Point *D*, Equation (23*b*) for Line *D P* yields $x = -0.763859\,y - 3\,172.4$; and, solving for x, $x = -0.58348\,x + (-0.763859 \times -19\,699.5) - 3\,172.4 = \dfrac{+11\,875.2}{+1.58348} = +7\,499.5$; and, $y = (+0.763859)(+7\,499.5) - 19\,699.5 = -13\,971.0$ (see Case I, Fig. 5). A form sheet for the foregoing computation (see Table 4) makes the solution straightforward, and with the aid of natural functions and a computing machine, the computation can be made in 5 min.

As the author states, the analysis of data on multiple pointings involving more than three stations brings in many possible solutions. It will be noticed that in the foregoing analysis any station (*D*, for example) may be taken for the central, or reference line. If perpendiculars are taken, and auxiliary points, such as *E*′, etc., are computed for each pair of points (such as *ED*), a series of such auxiliary points will range along the true line passing through Point *P* and normal to Line *DP*. Using the author's data Table 5 gives such results. A first approximation is the "range-line," *C*′ *E*′:

TABLE 5.—STATIONS REFERRED TO STATION *D*, CO-ORDINATES; *N* − 12 618.6; AND, *E* + 6 466.4

B′......				−6 007.5	+1 247.5	−20 425.1	−949.2
C.......	312° 24′ 48″	+1 031.5	−26 010.1			−11 587.1	−19 543.7
C′......				−23 761.6	−942.3	−35 348.7	−20 486.0

Co-Ordinates *C*′..........	− 35 348.7	− 20 486.0
Co-Ordinates *E*′..........	− 7 628.5	+ 15 802.7
Change..................	+ 27 720.2	+ 36 288.7

and, the slope, m, $= \dfrac{+27\,720.2}{+36\,288.7} = +0.763880.$

Using the co-ordinates of Point *E*′, the equation of the "range-line" is,

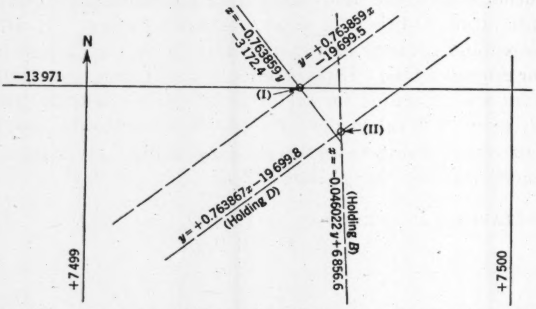
$$y = +0.763880\,x - 19\,699.9 \qquad (25)$$

When the values of x for each of the auxiliary points is substituted in Equation (25) and the y-value computed, the departure of the value in Table 5 can be ascertained. Since the line passes through Points *E*′ and *C*′ these departures are zero. The other departures are *F*′, + 0.4; *O*′, − 1.0; *A*′, + 0.5; and, *B*′, − 0.1. The departure of the value for *O*′ is considered as excessive and is rejected. A new line may be chosen that will more nearly equalize the departures of the tabulated data. Such a line would pass 0.3′ north of Point *C*′ and

0.1′ south of Point E'. This can be seen on a graph of exaggerated scale (Fig. 6) in which "x (East)" is plotted: 1″ = 5 000 ft; and, "difference of y (North)" = 1″ = 1 ft (the scale in Fig. 6 has been reduced for publication). The new equation for the "range-line" would then be,

$$y = +\,0.763867\,x - 19\,699.8 \quad \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Since Station D may have been in error, it will be necessary to choose another "range-line," a quadrant removed from the pointing to D. Consider, for example, a set of data referred to Station B and determine a range line that will distribute the computed errors approximately equally on either side. An analysis gives a line normal to Line $P\,B$ having the equation,



N
−13 971
x = −0.763859 y −3 172.4
y = +0.763859 x −19 699.5
(I)
(II)
y = +0.763867x −19 699.8 (Holding D)
x = −0.046022 y + 6 856.6 (Holding B)
+7 499
+7 500

FIG. 5.—SOLUTION BY ANALYTIC GEOMETRY: CASE I = SIMPLE 3-POINT FIX; AND CASE II = BALANCED 6-POINT FIX

$$x = -\,0.046022\,y + 6\,856.6 \quad \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

and the solution of the two equations for x and y (Case II, Fig. 5) gives the probable position of the point as: North − 13 971.1; and, East + 7 499.6.

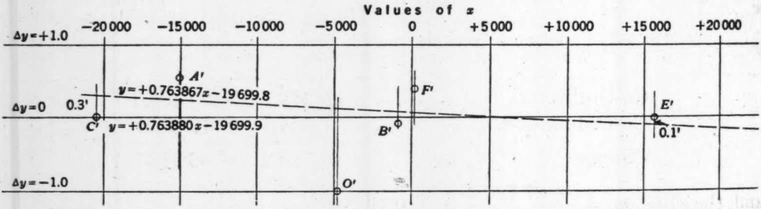


FIG. 6.—POSITION OF AUXILIARY POINTS WITH RESPECT TO "RANGE-LINE"

The writer feels that the careful use of the "three-point-problem" can have a distinct value in giving an independent check on survey work, particularly in certain types of reconnaissance work where it may not be economically possible to loop the survey into closed traverses. For this purpose it would be necessary, of course, to refer the co-ordinates of the basic control stations to the meridian of the initial station.

R. ROBINSON ROWE,[6] M. AM. SOC. C. E. (by letter).—The limited discussion of this paper may be summarized as: (1) Acceptance of the principles and formulas as correct; (2) statements of particular cases for which the methods are, or are not, adaptable; (3) doubt that the proposed method for the reduction of a four-point problem (or more) is economical; and (4) alternate forms for tabulating the solutions. The writer desires to express his appreciation of the thoughtful and helpful contributions of Messrs. Adams, Whitmore, and Jahn; with them, he is in substantial agreement.

---

[6] Associate Bridge Engr., State Dept. of Public Works, Sacramento, Calif.

Mr. Adams has stressed the increasing availability of co-ordinated spires in certain localities. His further comment on precision of co-ordinates would have been in point; but, regardless of original precision, spire co-ordinates cannot be considered valid until some check has been effected, due to deflection of structures. When so checked, however, accuracy sufficient for the next lower order of survey can be assured. If Mr. Adams implied the contrary in his final sentence, the writer cannot agree.

For example, the probable error of the location P_2 was not greater than 0.16 ft (0.13 + 0.03 ft), which is less than one-ten-thousandth part of the distance from the nearest spire and a much smaller part of the distance from the nearest instrument point of the prior triangulation. If another point, say 1 mile from P, were to be fixed in similar fashion, and if these two points were connected by traverse with satisfactory closure, all points of the survey should merit a fourth-order rating.

Spire co-ordination by the U. S. Coast and Geodetic Survey should be appreciated by surveyors because of their instant availability. Not only are instrument stations of the Survey often obliterated or covered by buildings, but residential construction on eminent hills frequently interferes with important sight lines.

The writer agrees with Mr. Whitmore that a five-point fix can be adjusted rapidly by the least squares method, if computers are familiar with the method and the five points are proved; but if one of the five points is rejectable, the method may introduce fallacy. Furthermore, if Mr. Average Surveyor should have occasion to adjust such a fix once in a year, or twice in a lifetime, he would probably select three points by "eeny-meeny-miny-mo," with one chance in ten of selecting the strongest figure. The semi-graphical method should appeal to him; admittedly, the writer's example would have been more clear if only five points had been studied.

Mr. Jahn has suggested an additional use for the three-point fix—the recovery of old instrument stations which had been referenced to several spires. Probably he refers to buried monuments, and for such objects the point is well taken. It was interesting to learn that he had also conceived of an instrument sight line as a band rather than the conventional geometric line; the width of the band should not be a "unit," but should be proportional to the probable error. His alternate computation forms and method of adjusting three-point and six-point fixes are worthy of consideration. Although the writer still prefers his own, he realizes that each computer will find certain arrays of figures more natural to his psychophysical processes. Although Mr. Jahn's six-point solution departs from the least squares solution by 0.11 ft (compared to 0.03 by the method of the paper), the lesser precision may be adequate and obtainable more economically.

TRANSPORTATION OF SAND AND GRAVEL IN A FOUR-INCH PIPE

By G. W. Howard,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Fred R. Brown, Josef E. Montgomery, Elliott J. Dent, David L. Neuman, Morrough P. O'Brien and R. G. Folsom, R. L. Vaughn, M. P. Durepaire, Pierre F. Danel, H. S. Gladfelter, and G. W. Howard.

Synopsis

Tests on 4-in. pipe, transporting water mixed with sand and small gravel, are described in this paper. Although a description of the flow characteristics of sand and water mixtures and gravel and water mixtures in a 4-in. pipe constitutes the main part of the paper, an attempt is made to generalize the findings in regard to other sizes of pipe in so far as it is believed to be applicable. A discussion is given of existing general formulas for the transportation of materials in pipe lines, and it is attempted to prove that the type of material to be transported and the experience of the designer should have more bearing on the solution of a problem than any solid-transportation formula now extant.

No new formulas are presented. An insufficient number of investigations have been made to justify the use even of the formulas now in existence. The attempt is made, however, to consolidate all known facts concerning the transportation of sand and water mixtures in order to show that, at present, only general characteristics can be determined for this phenomenon.

Introduction

One of the earliest discussions on the transportation of sand mixtures in pipes is given in a paper entitled "Works for the Purification of the Water Supply of Washington, D. C.,"[2] by the late Allen Hazen and E. D. Hardy, Members, Am. Soc. C. E. Only a brief treatment is presented in the paper, however, because the topic of sand transportation in filter washing is incidental to the primary subject. The pipes for which friction curves are given had diameters of 3 and 4 in. Types of transportation and other flow characteristics

are not considered, as friction losses were the only features that were of interest. A discussion of the paper of Messrs. Hazen and Hardy by Nora Stanton Blatch, Jun. Am. Soc. C. E., provides more definite data than any other available reference on the subject.[3] Using the results from tests on 1-in. pipe as a basis for her discussion, Miss Blatch compared the data of Hazen and Hardy with additional data from the Mississippi River Commission on the dredges *Alpha*, *Beta*, and *Gamma*. Due to the fact that the test line was equipped with a transparent section, Miss Blatch covered, in detail, the types of movement that occur at different velocities. An analysis of all data led to a general formula for head loss in pipes ranging in diameter from 1 in. to 32 in., and for all variations of solid concentration. Her findings are generally used as references in textbooks on hydraulics.[4]

The data available from pipe-line dredges are so few that it might be considered surprising until the difficulties in making accurate field measurements are considered. Unstable pumping conditions with subsequent variations in pipe-line velocities and solid concentrations make data of this nature extremely difficult to correlate. Due to the fact that the load in the pipe line of a dredge varies so frequently, it is almost impossible to obtain consistent pressure-gage readings; therefore, an average value of velocity and solid concentration is all that can be hoped for in tests on large pipe lines. Discussions of tests on pipe-line dredges have been presented more frequently in recent years,[5] but no sets of curves, such as were presented by Miss Blatch, have been included in any of these papers.

Although friction losses for pipe lines of hydraulic dredges have been determined,[6] few instances have occurred in which these lines were loaded with solids. Since actual design work for this plant must consider the material that is being moved, the losses found for water alone have definite limitations.

The purpose of this paper is to present the findings from tests on 4-in. pipe carrying varying concentrations of sand and gravel. These findings are believed to be of general interest to those engaged in work dealing with the transportation of solids through closed conduits, and the results presented herein are given with the view of advancing the limited knowledge in this field.

Program of Experiments

Two separate series of tests were performed, each on a different material. The investigation of the sand and water mixtures was more complete than that of the gravel mixtures. This was due to the fact that the specific purpose of the gravel experiments, to which the data presented herein are only incidental, had been limited in scope, because of findings from the sand tests. During each series the following conditions were varied within certain limits: (*a*) Pipe-line velocities; and (*b*) solid concentrations.

DESCRIPTION OF THE APPARATUS

General.—The apparatus used to maintain a constant solid concentration consisted of a sump, a pump, and a variable head tank that discharged through the 4-in. test line back into the sump. This caused a uniform circulation of any mixture and provided a means for obtaining constant pressure and an even distribution of solids over the cross-sectional area of the pipe. The arrangement of this apparatus is shown diagrammatically in Fig. 1.

FIG. 1.—APPARATUS USED ON TESTS FOR SAND AND GRAVEL

Test Line.—Starting from the variable head tank the 4-in. line extended 8 ft horizontally and then curved downward and reversed its direction through two 90° ells. The upper 8-ft section was equipped with a positive-action cock to give control over the lower velocities. After reversing direction, the 4-in. line extended a distance of $86\frac{1}{4}$ diameters and discharged into the sump. The lower $43\frac{1}{3}$ diameters of the line were used as the test section. Two 2-ft sections of transparent pyralin pipe were installed in the test line and three open-end manometers were connected to the test section. Due to the fact that considerable material was usually carried on the bottom of the pipe, it was not considered practical to use a manometer ring or four manometer taps. Two openings, at 45° with the horizontal plane, were used at each connection. The up-stream connection was 43$\frac{1}{3}$ diameters from the end of the line, and the lengths of the other connections were varied for different tests; the readings of these two gages were used as a check on the up-stream manometer.

Solid Concentration Determination.—The device used to determine the percentage of solids of the mixture consisted of a volumetric basin supported on scales. A diversion trough, which was moved under the end of the pipe when samples of the mixture were taken, was attached to the volumetric basin.

Concentrations of material over the cross-sectional area of the pipe were determined by inserting a tube, $\frac{7}{16}$ in. in diameter and bent to an angle of 90°, into the end of the pipe. To insure comparable locations for all samples, the pipe was held in place by a plate that could be raised or lowered between two hinges in order to give vertical control. Horizontal control was secured by a wing nut which held the tube firmly in place. Three ranges across the pipe were used for observations: One at the center of the pipe, and the other two at one-half the distance to the edge of the pipe on either side of the center range. This apparatus is shown in Fig. 2.

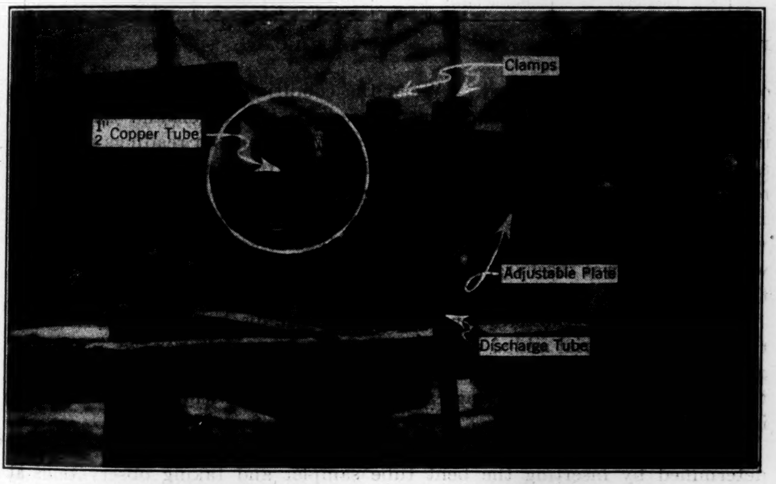

FIG. 2.—APPARATUS FOR DETERMINING THE CONCENTRATION OF SOLID MATTER

PROCEDURE OF EXPERIMENTATION

The material tested is known at the United States Waterways Experiment Station as Pearl River sand, an analysis of which is shown on Fig. 3. The gravel in Fig. 3, known locally as "pea gravel," had the general specification that no particle should be larger than $\frac{1}{4}$ in.

Sand Tests.—The velocity was first set at about 5 ft per sec and a solid concentration introducd into the circulating system that caused about 10 lb per sec to be discharged at this velocity. (The percentage of solids used for these investigations was apparent; that is, included water in the voids. This resulted in a specific gravity for wet sand of 2.08 and wet gravel of 1.94, instead of the 2.65 customarily used.) When the condition had been obtained and checked, a complete set of manometer readings was taken and the velocity increased to about 6 ft per sec. Another set of manometer readings was taken at this increased velocity. In this manner the data for the complete velocity range obtainable with the apparatus were obtained for a sand discharge of 10 lb per sec. The equilibrium set up in the system was such that, when the velocity was increased, although the percentage of solids decreased, the same weight of sand was discharged. Clear water was used in the manometers and this pressure was later converted to feet of mixture of the solid concentration.

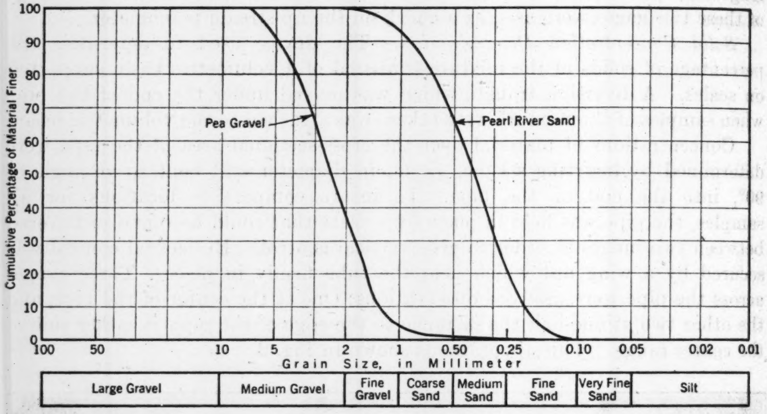

Fig. 3.—Mechanical Analysis of Pearl River Sand and Pea Gravel, Tested in a Four-Inch Pipe

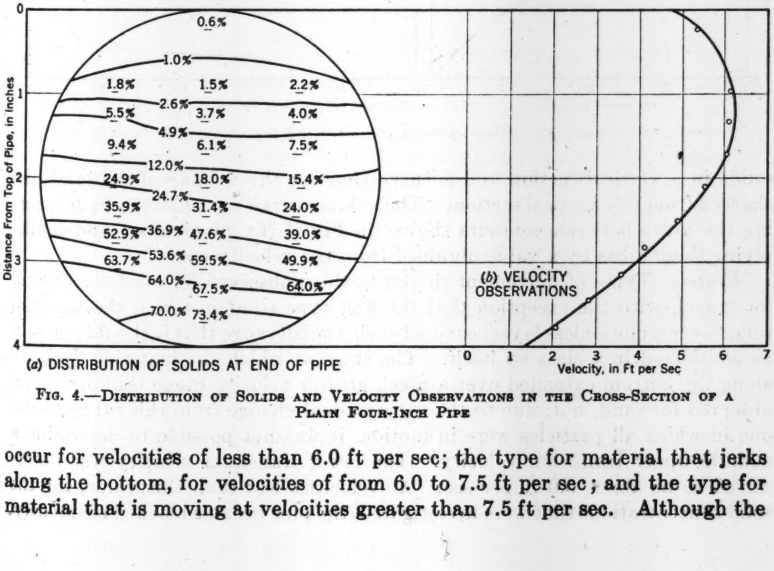
After obtaining the data for the 10-lb per sec discharge, the velocity was reduced and material added until the discharge was 15 lb per sec. The foregoing testing procedure was followed, for the new sand discharge, throughout the entire range of the carrying capacity of the pipe, with the sand discharge increased in 5-lb increments.

The distribution of solids over the cross-sectional area of the pipe was determined by inserting the bent tube sampler and taking observations at different places in the section. Besides obtaining data for the percentage of solids passing a certain point, information was also obtained relative to the velocity in the pipe at that location.

Gravel Tests.—The primary difference between these tests and the sand tests lay in the fact that the testing range was considerably decreased. Velocities of from about 5.5 to 8.5 ft per sec constituted the entire range covered in the investigation. Since an equilibrium similar to that obtained during the sand tests occurred during this investigation, it was possible to observe the entire velocity range for any given weight of material discharged without changing the quantity of gravel in the circulating system. Gravel discharges of from 10 to 30 lb per sec were used and the same test routine was followed as that used for the investigation of sand. Considerably more difficulty was experienced in obtaining check readings for these tests on gravel than for those with sand. The distribution of solids over the cross-sectional area could not be obtained on account of the fact that the size of the gravel was such that it would plug the sampling device. Although the particles would enter the tube, the curved outlet caused blocking.

Method of Transporting the Material

Sand.—Three distinct types of transportation were found for sand and water mixtures in pipes. The first of these was at low velocities, where practically all material was on the bottom of the pipe. A layer of sand was built up and the material rolled over this bed in much the same manner as in an open flume. The second type of movement was one in which the sand layer that was built up at low velocities would move forward slightly and then halt, while other material would still move freely over this bed. This spasmodic movement can be termed most correctly, "jerking," because the material along the bottom moved freely one instant and was quiet the next. The third type was one in which the material was moving over the entire cross-sectional area, although the greater percentage was concentrated in the lower part of the pipe. These three types of movement cause head-loss determinations for sand and water mixtures naturally to be quite complex, because of the indeterminate line of differentiation. For a 4-in. pipe transporting the sand that was used in the studies at the U. S. Waterways Experiment Station, the type of movement in which the material is on the bottom of the pipe will generally occur for velocities of less than 6.0 ft per sec; the type for material that jerks along the bottom, for velocities of from 6.0 to 7.5 ft per sec; and the type for material that is moving at velocities greater than 7.5 ft per sec. Although the



(a) DISTRIBUTION OF SOLIDS AT END OF PIPE

Fig. 4.—Distribution of Solids and Velocity Observations in the Cross-Section of a Plain Four-Inch Pipe

foregoing values will vary somewhat with solid concentrations, it is possible to use them for general purposes.

The manner in which the material is concentrated over the cross-sectional area is shown in Fig. 4, together with the variation of vertical velocities. These velocity observations are considered as weights rather than true values because it was not possible to obtain a satisfactory calibration of the sampling device, due to the variation of the solid concentrations, coefficient of friction, and mean grain size of material transported at various locations in the pipe. General data relating to these observations are:

Solid matter discharged, in pounds per second	14.6
Percentage of solids	14.4
Velocity of flow in pipe, in feet per second	8.88

Although it can be seen that the greater concentration of material is on the bottom of the pipe, this does not mean that the greater quantity of material is carried in this area. Fig. 5 presents a curve showing the distribution of solids in a vertical section and a curve showing the volume of material discharged from this vertical section. The volume curve was obtained by measuring the areas between contours shown on Fig. 4 (by planimeter) and multiplying these areas by a value obtained from the velocity curve.

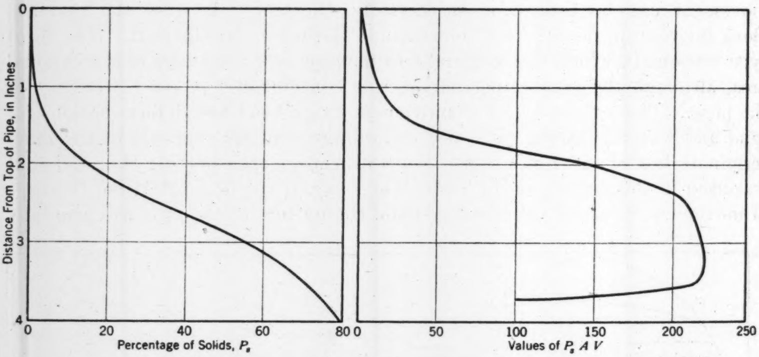


FIG. 5.—CURVES OF SOLID CONCENTRATION AND QUANTITY OF MATERIAL DISCHARGED

Gravel.—Types of movement similar to those observed for sand were found for gravel, with the exception that the first type (that in which the material rolled over a motionless layer) covered such a small range that it should scarcely be considered in a class by itself. The stage at which the material "jerked" along the bottom extended over a much greater velocity range than had been observed for sand, but, due to the very gradual change from this range to the one in which all particles were in motion, it was not possible to determine a definite upper transition velocity. The lower transition velocity was determined to be about 5.0 ft per sec. At velocities less than this value, for the solid concentrations that were investigated, the pipe became blocked frequently.

This was caused by the lower gravel particles becoming motionless on the bottom and the other particles piling rapidly on top of each other instead of rolling along over a motionless layer as did the sand particles.

HEAD LOSS VARIATIONS

Curves showing changes in head loss for sand and gravel mixtures in the 4-in. pipe are presented in Fig. 6. These curves show tendencies that are to be expected from the aforementioned types of movement. At velocities where material is settled or greatly concentrated on the bottom, there is a greater head loss per foot of pipe than for slightly higher velocities, because of the pressures created by the constriction of the cross-sectional area. The minimum head loss was obtained during the velocity range in which the jerking movement occurs, since the constriction was being removed. Curves of the losses for sand (Fig. 6(*a*)) show this condition more clearly than do those for gravel (Fig. 6(*b*)), because of the small velocity range investigated for gravel and the fact that gravel was found to travel along the bottom in a high concentration at all velocities. The curves for sand show points of minimum loss and the gradual increase in head loss at high velocities. The gravel curves, however, show only the great losses found at low velocities and the gradual decrease in head loss for a corresponding increase in velocity.

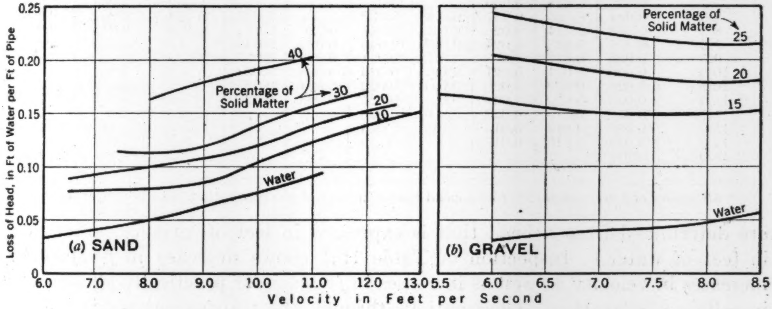

FIG. 6.—HEAD LOSS CURVES FOR VARIOUS SAND AND GRAVEL MIXTURES

When applied to water, exponential pipe formulas are more accurate than the Darcy formula,

$$h_f = \frac{f\,L\,V^2}{2\,g\,D} \qquad (1)$$

which fact more than offsets the extra computation required. Changes in head loss for pipes carrying sand or gravel ,however, can best be shown by the formula,

$$f = \frac{2\,g\,D\,h_f}{L\,V^2} \qquad (2)$$

and the results from an investigation of *f*-values will be presented before consideration is given to any exponential formulas. (In Equations (1) and (2): h_f = loss of head due to friction; f = a friction factor; L = length of pipe, in feet; V = average velocity, in feet per second; g = acceleration due to gravity; and D = mean inside diameter of pipe, in feet.)

The Common Formula for Head Loss.—Values of f for various concentrations of material are presented in Table 1. (It should be noted that these values are determined from a head that is expressed in feet of mixture rather than in feet of water.) Inspection of Table 1(*a*) shows decrease in f-values for increases in velocity as well as increases in f-values for practically all increases in solid concentration. Observations through the transparent section of the pipe indicated that these variations in f could be expected, because of changes in transportation characteristics that were observed.

* All values of f are computed from a head that is in feet of mixture rather than in feet of water.

Investigation of the variation of f-values when gravel was transported shows characteristics similar to those obtained for sand. These values are shown in Table 1(*b*). The changes in values of f can be seen to follow the same trends that were found for sand.

Investigation of the 1-in. pipe by Miss Blatch and the 3-in. and 4-in. pipe of Hazen and Hardy shows tendencies similar to those obtained from the 4-in. pipe at the U. S. Waterways Experiment Station. Computations of *f*-values, made for the 1-in., 3-in., and 4-in. pipes are presented in Table 2. The weight of wet sand in these tests was assumed equal to 129.5 lb per cu ft.

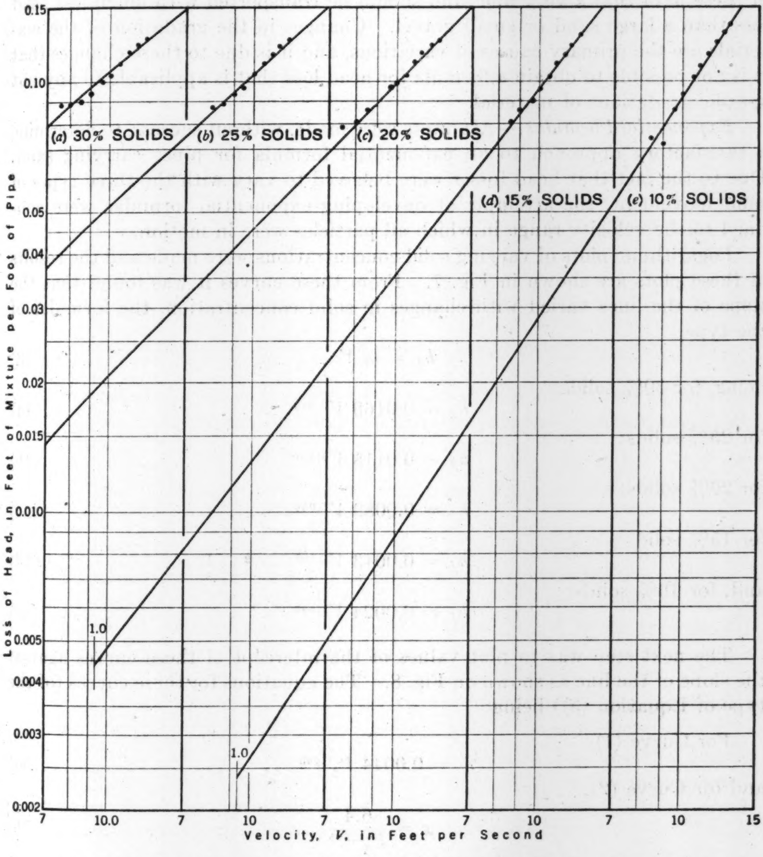

FIG. 7.—LOGARITHMIC PLOT OF HEAD LOSSES FOR VARIOUS SAND CONCENTRATIONS

The only data available for *f*-values in clear water referred to the 1-in. pipe, and these values were found to range from 0.037 at 3.0 ft per sec to 0.035 at 11.0 ft per sec. Values of *f* for the 4-in. pipe at the U. S. Waterways Experiment Station varied from 0.0206 at 5.4 ft per sec to 0.0164 at 11.2 ft per sec.

Results from the 4-in. pipe for the Hazen and Hardy investigations cannot be compared with data obtained at the U. S. Waterways Experiment Station, because of the differences in pipe and sand. The test pipe described herein has two 2-ft pyralin sections and one 2-ft sheet metal section in the test line. No sand analysis curves were presented in the Hazen and Hardy paper.

These results show the differences that can be expected in head losses due to the type of material that is being transported. It can be seen from a review of these data that a very fine sand should be transported with much less head loss than a large sand or small gravel. Changes in the gradation of the materials are the primary causes of variations, and it is due to these changes that it is not possible to obtain a formula for head loss that is applicable to any but specific gradations of material.

Exponential Formulas.—Attempts were made, without success, to determine a satisfactory approach to an exponential formula for pipes carrying sand. Due to the fact that head losses were believed to vary with the three types of sand movement, the attempts at developing exponential formulas were confined to the velocity range in which all particles were in motion.

Logarithmic plots of varying solid concentrations were made and the results of these plots are shown in Fig. 7. From these curves it was found that the slope of the lines varied with changes in solid concentration, the formulas of the type,

$$h_f = m\,V^x \qquad (3)$$

being, for 30% solids:

$$h_f = 0.0160\,V^{0.830} \qquad (4a)$$

for 25% solids:

$$h_f = 0.0118\,V^{0.950} \qquad (4b)$$

for 20% solids:

$$h_f = 0.0089\,V^{1.050} \qquad (4c)$$

for 15% solids:

$$h_f = 0.0043\,V^{1.360} \qquad (4d)$$

and, for 10% solids:

$$h_f = 0.0024\,V^{1.590} \qquad (4e)$$

The next step was to plot values of the intercept of these curves against the slope of the line as shown on Fig. 8. The equations for these curves (of the type of Equation (3)) being:

For Curve (1),

$$m = 0.0044\,P_s^{1.740} \qquad (5a)$$

and for Curve (2),

$$x = \frac{6.4}{P_s^{0.595}} \qquad (5b)$$

(In Equations (5*a*) and (5*b*): m = the intercept; P_s = the solid concentration; and x = the exponent for the general equation.) Although this action provided a satisfactory set of curves which were applicable to all solid concentrations, it was realized that this formula would yield data that were satisfactory for only one size of pipe transporting only one particular class of sand. A family of curves might yield data applicable to general cases, but the foregoing data considered only one of the types of movement. Since data were lacking for all

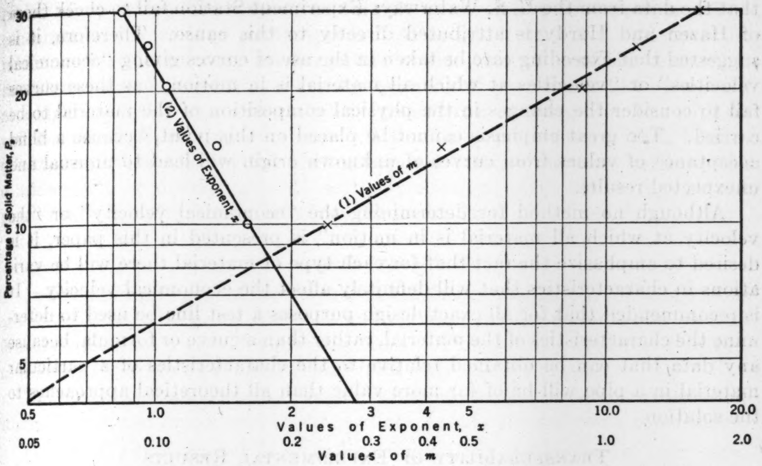

FIG. 8.—LOGARITHMIC PLOT OF EXPONENT AND m-VALUES FOR VARIOUS SAND CONCENTRATIONS

except one set of curves, and it was believed that this method would result in more complications relative to transition velocities for the types of movement, efforts to obtain an exponential formula were abandoned.

THE ECONOMICAL VELOCITY FOR SAND TRANSPORTATION

The velocity at which any given volume of sand per hour can be transported through a given length of pipe with the least expenditure of power per unit volume of sand transported, has been called by Miss Blatch[7] the "economical velocity." Curves taken from diagrams in her discussion can be found in several references on sand transportation, and it is the information contained in these curves rather than the definition itself that will be treated herein.

In order to determine an economical velocity for transporting material in any given size of pipe, the following factors should be considered: (1) The length of line to be used; (2) the energy required to produce the desired velocity; (3) the type of material to be transported; and (4) the solid concentration that will cause a minimum loss of head at the velocity that is desired. The resultant economical velocity, therefore, is a delicate balance among these factors.

Of the aforementioned considerations, it is believed that the type of material to be transported, Factor (3) is most pertinent. A comparison of Figs. 6(*a*) and 6(*b*) shows clearly the great effect on head loss that will result from variations in gradation of the material. These differences in grain sizes have a decided effect on all transportation characteristics and the results obtained from one class of material cannot be expected to hold for another. The fact that the data from the U. S. Waterways Experiment Station fail to check those of Hazen and Hardy is attributed directly to this cause. Therefore, it is suggested that exceeding care be taken in the use of curves giving "economical velocities" or "velocities at which all material is in motion," as these curves fail to consider the changes in the physical composition of the material to be carried. Too great emphasis cannot be placed on this point, because a blind acceptance of values from curves of unknown origin will lead to unusual and unexpected results.

---

[7] *Transactions*, Am. Soc. C. E., Vol. LVII (1906), p. 406.

Although no method for determining the "economical velocity" or "the velocity at which all material is in motion" is presented in this paper, it is desired to emphasize the fact that for each type of material there will be variations in characteristics that will definitely affect the economical velocity. It is recommended that for all exact design purposes a test line be used to determine the characteristics of the material, rather than a curve or formula, because any data that can be obtained relative to the characteristics of a particular material in a pipe will be of far more value than all theoretical approaches to the solution.

TRANSFERABILITY OF EXPERIMENTAL RESULTS

Results from the investigations on 4-in. pipe cannot be applied, by means of any model law, to larger pipe used in dredging. General variations of type of movement, head losses, and method of transportation, discussed previously, occur in a similar manner in larger pipe. Because of the constant variations in the material pumped by dredges, the results from 4-in. pipe can be considered only qualitatively, when applied to the larger pipe lines. Velocity determinations in regard to the ranges of the different classes of movement are of primary importance in attempting to apply results from smaller pipe to the larger sizes. Observations through the transparent section of the test line showed that a velocity range of from about 5.0 ft per sec to 8.5 ft per sec in the 4-in. pipe would cover all types of movement that occur in the discharge lines of dredges. It can also be expected that, depending on the length of the discharge line of the dredge, the material in the line will move in accordance with one of the three types of movement previously described. For long discharge lines, where the velocity drops to about 14 or 15 ft per sec in a 32-in. line, or to 9 or 10 ft per sec in a 20-in. line, the material will settle on the bottom of the pipe, provided sand is being pumped. As the length of the line is decreased and the velocity is correspondingly increased, the types of movement change until the material is being literally blown through the line, passing through exactly the same stages of transportation as those found in the 4-in. pipe.

The determination of an economical velocity for the discharge lines of dredges cannot be made directly from characteristics of the transported material, however, because it is usually true that power developed by the pumping machinery and the fuel consumption have more bearing on this velocity than head losses in the line. This fact makes the economical velocity for each dredge an individual problem which cannot be solved until a sufficient period of operation has elapsed to furnish data relative to output and fuel consumption for various pump speeds. Although it can be found that the minimum head loss for the discharge line would occur at a certain velocity, it must also be considered that a greater quantity of material might be moved, at a higher velocity and with a slightly greater fuel consumption, but with no real increase in operating overhead. It can be seen, therefore, that, besides the theoretical conditions for the economical velocity in the pipe line, the consideration of operating costs and depreciation must necessarily play a greater part in determining velocities for use in large pipe lines.

CONCLUSIONS

In attempting to generalize the findings of this investigation, the conclusions are confined to a range in which as many statements as possible can be confirmed by data from previous investigations. This is done, whenever possible, to prevent the forming of conclusions from only one set of data.

The investigations described herein, with information available from other studies conducted on somewhat similar lines, justify the following conclusions:

(1) Sand is transported in pipes by rolling along the bottom at low velocities, "jerking" along the bottom at medium velocities, and by having all particles in motion at velocities greater than the range in which "jerking" occurs;

(2) The largest quantity of material is transported in the lower third of a pipe rather than along the bottom;

(3) For pipes carrying sand, values of f in Equation (1) will decrease with an increase in velocity;

(4) Values of f will increase with an increase in solid concentration, for any velocity;

(5) A general formula for use in determining head loss in pipes carrying sand is definitely dangerous for use by any person who has not had considerable experience with the use of the formula;

(6) The economical velocity for transporting solids depends upon the character of the material to be carried, and each class of material will probably have a different economical velocity for the same size of pipe;

(7) A pipe line, transporting material of a large grain size at low velocities, will become blocked much more frequently than pipes carrying material of a small grain size, because the larger particles tend to become locked, obstructing other particles, and do not form a smooth bed over which the material can move; and,

(8) The transfer of results from a small pipe line to a line of greater diameter must be qualitative and not governed by any law of corresponding velocities.

ACKNOWLEDGMENTS

The investigations described herein were conducted at the U. S. Waterways Experiment Station, at Vicksburg, Miss., in connection with an investigation dealing with methods of increasing the capacity of pipe lines transporting

solids. They were made under the direction of F. H. Falkner, Lieutenant, Corps of Engineers, U. S. Army, Jun. Am. Soc. C. E. The writer wishes to thank the present Director of the Station, Paul W. Thompson, Lieutenant, Corps of Engineers, U. S. Army, Jun. Am. Soc. C. E., for his co-operation in making this paper possible and for suggestions in connection with its preparation. He also wishes to thank Joseph B. Tiffany, Jr., Jun. Am. Soc. C. E., and V. G. Kaufman, for reviewing the contents prior to final assembly.

DISCUSSION

Fred R. Brown,[8] **Jun. Am. Soc. C. E.** (by letter).—Despite the findings of recent worth while investigations, the information on the transportation of material in pipe lines is still rather meager. Hence, there are not at hand data sufficient for the development of a formula with comprehensive application to the movement of solids through pipe lines. If such a formula can be determined its development can follow only upon the collection of further data, and the correlation of these data with those previously obtained.

TABLE 3.—Variations in Friction Factor, *f*, for Changes in Solids Concentration in a Thirty-inch Pipe

Velocity, *V*, in feet per second	Values of *f* for the Following Percentages of Solid Matter:			Velocity, *V*, in feet per second	Values of *f* for the Following Percentages of Solid Matter:			Velocity, *V*, in feet per second	Values of *f* for the Following Percentages fo Solid Matter:		
	Clear water	10	20		Clear water	10	20		Clear water	10	20
(1)	(2)	(3)	(4)	(1)	(2)	(3)	(4)	(1)	(2)	(3)	(4)
4	0.030	....	0.265	8	0.025	0.052	0.074	12	0.022	0.029	0.043
5	0.029	....	0.175	9	0.025	0.043	0.063	13	0.022	0.028	0.039
6	0.027	....	0.125	10	0.024	0.038	0.053	14	0.021	....	0.037
7	0.026	....	0.094	11	0.023	0.032	0.047	..	....	....	....

It is with this point in mind that the computations in Table 3 are offered. The data for these computations were taken from the curves of the dredge *Alpha*,[9] presented in the discussion by Miss Blatch,[7] and bear out Mr. Howard's findings on 1-in., 3-in., and 4-in. pipes in that the friction factor in pipes transporting material increases with the percentage of material and decreases with the velocity. These values of *f* may be incorporated in Table 2, compiled by Mr. Howard, thus presenting *f*-values in 1-in., 3-in., 4-in., and 30-in. pipes. All values in Table 3 are computed from a head that is in feet of mixture rather than in feet of water.

The magnitude of velocities and the percentage of solids used in deriving the foregoing *f*-values were determined by the volumetric method. Velocities obtained by other methods (salt solution, gage stick, etc.), for pipes transporting material not in suspension, are not true average velocities. Hence, such velocities will introduce appreciable errors in any computations involving velocity. Likewise, there are numerous ways of determining the percentage of solids pumped, but percentages determined by volumetric measurement are the most accurate. Errors in velocity or the percentage of solids will increase as the percentage of solids increases, if other than the volumetric method of measurement is used. For this reason, any data that might be incorporated with those of Mr. Howard in an attempt to arrive at a formula for pipes transporting material should have the velocities and the percentages of solids determined volumetrically. Data obtained otherwise would not be comparable with that presented so ably by Mr. Howard.

[9] "Dredges and Dredging on the Mississippi River," by the late J. A. Ockerson, Past-President, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. XL (December, 1898), p. 215.

JOSEF E. MONTGOMERY,[10] **ESQ.** (by letter).—One of the most interesting points developed by Mr. Howard is that which shows the increase in values of Darcy's *f* with decrease in velocity for flow in a 4-in. pipe carrying water and entrained sand or gravel. Below certain values, the relation of *f* to velocity is much different for solids-laden water than for clear water. The cause of this difference is shown by comparison with *f*-values for flow of clear water in similar pipes. Data suitable for such comparison are found in the results of previous work[11] by Fred C. Scobey, M. Am. Soc. C. E., published in 1930. Using the data obtained by Mr. Scobey, curves have been plotted in Fig. 9 to show the relation of values of *f* in Equation (2) to mean velocity for the flow of clear water in a 4-in. pipe. Representative data obtained by Mr. Howard have been likewise plotted. At higher velocities all values approach the same relation to velocity, although the scope of the investigation was not sufficient to provide for full comparison.

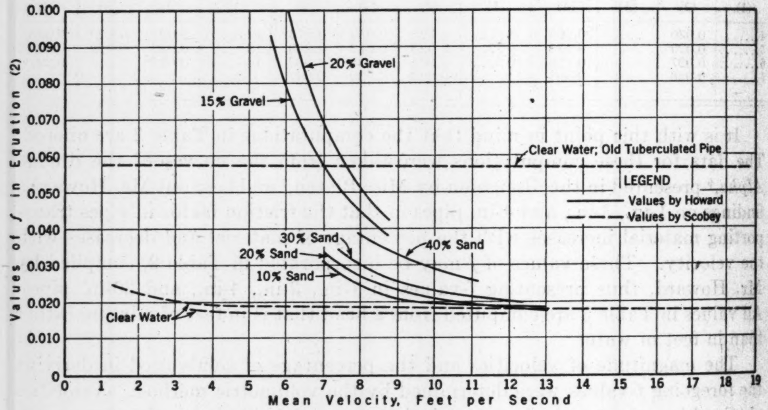

FIG. 9.—COMPARATIVE VALUES OF DARCY'S *f*.

The curves for the runs with gravel are least similar to the curves for clear water, but Mr. Howard states that some gravel remained motionless on the bottom during the full range of velocities observed. Curves for the sand approach those for clear water, and two of the curves coincide at higher velocities. It is apparent that the highest values of *f* occur for the lowest velocities and highest solids concentration, in which some solid material was observed to be at rest on the bottom of the pipe. The relation of *f*-values to velocity for sand-laden water approaches that for clear water in those runs in which all material was known to travel in suspension.

[11] "The Flow of Water in Riveted Steel and Analogous Pipes," by Fred C. Scobey, *Technical Bulletin, No. 150,* U. S. Dept. of Agri., Washington, D. C., pp. 35 and 38.

The data show that entrainment of solids (that is, sand or gravel) is not alone sufficient to produce appreciable effect on the variation of *f* with velocity, but that it is deposition of such material at the bottom of the pipe that affects the relation. This change is not due to the pressures created by constriction of cross-sectional area, as stated by Mr. Howard under "Head Loss Variations," since the friction factor, *f*, is generally unaffected by pressure changes. The explanation is found in the fact that values of *f* are very sensitive to any deviation from the nominal area value used in the computation of this coefficient.

Comparisons of this type can be put to practical use in dredging and similar operations because they indicate the possible existence of motionless solids on the bottom of a pipe and the consequent waste of energy. Curves of the type shown for gravel in Fig. 9 show the excessive energy loss due to insufficient velocity for that particular concentration. If extended by additional data, these curves would indicate further the optimum velocity for transportation of such material.

ELLIOTT J. DENT,[12] M. AM. SOC. C. E. (by letter).—This paper is of particular interest to the writer as it supplies a more complete picture of the manner in which sand and water mixtures flow through pipe lines than any of the reports that had previously come to his attention. With the information presented, combined with that previously available, and combined further with data furnished by Mr. Howard by letter, it is possible to picture the behavior of quite a wide range of mixtures flowing in a 4-in. pipe. Although such a portrait may not be applicable to full-sized dredge pipes in a quantitative sense, the data do afford a qualitative picture for the benefit of dredge designers and operators. These laboratory results will also constitute an excellent guide for the preparation of a program for further investigations.

The author emphatically calls attention to the effect of the size of the material handled, and gives an analysis of the sand and gravel used in the experiments reported upon. The importance of this feature cannot be overestimated and it is to be hoped that, in all future investigations, this practice will be continued. In this paper, as in most others on the subject, the friction losses due to the flow of water only have been inadequately described.

In a relatively unexplored field of this nature it is desirable that the factual data as well as the adjusted results be published. Students of the subject should be free to use their own methods for adjusting, compiling, and presenting the facts and the conclusions derived therefrom. For this subject there is no standardized system of presentation and, pending the time when a satisfactory system may be evolved, a wide variety of viewpoints is most desirable.

In this and other papers on the subject references are made to the manner in which the pipe lines are completely blocked off when the velocity falls below a certain value. The author has very kindly furnished the following data showing the blocking-off points in sand tests of a 4-in. pipe, for some of the mixtures handled:

---

[12] Col., U. S. Army (*Retired*), Washington, D. C.

Velocity	Percentage of sand concentration
5.7	26
7.0	27
7.5	34
8.2	52

In adjusting these data the writer has assumed that another point would correspond to a velocity equal to 00 and a percentage of solids equal to 00. The points were plotted and a smooth curve was drawn conforming as closely as possible to the data. The values for 15%, 20%, and 25%, were then taken from the curve. It is hoped that, in future investigations, the blocking-off points will be carefully established.

In presenting his adjusted data the author has reduced the losses of head to terms involving the specific gravity of the mixtures handled and has computed and tabulated the values of f in the Darcy formula. This method does not afford a simple or readily visualized picture of the case.

A formula for the loss of head, which is better known than Equation (1) of the paper, is the Chezy formula:

$$V = C\sqrt{R\,S} \qquad (6)$$

in which R = the mean hydraulic radius $= \frac{D}{4}$, in feet; S = the sine of the angle of slope $= \frac{h_f}{L}$; and, C = a factor often erroneously referred to as a constant.

Combining Equations (1) and (6):

$$V^2 = \frac{2\,g\,D\,h_f}{f\,L} = C^2\,R\,S \qquad (7)$$

Substituting S for its equivalent, $\frac{h_f}{L}$, and R for its equivalent, $\frac{D}{4}$:

$$V^2 = \frac{8\,g}{f}\,R\,S = C^2\,R\,S \qquad (8)$$

Therefore, $\frac{8\,g}{f} = C^2$; and, $f = \frac{8\,g}{C^2}$. It is obvious that phenomena that cause a variation in the values of C in the Chezy formula will cause corresponding variations in the values of f in the Darcy formula.

It is well known that, in the Chezy formula, the values of C vary with the slope, hydraulic radius, and roughness of the inner surface of the pipe. About two generations ago a formula for computing the value of C was devised and is known as the Kutter formula. It is laborious to solve and many tables and diagrams have been published to assist in this process. Similar tables and diagrams can be prepared for finding the values of f in the Darcy formula if it is desired to do so.

In dealing with the flow of water through pipe lines, the value of f is a complicated function of roughness, diameter, and slope. In dealing with the flow of mixtures of sand and water, the author has added to the complications by making f a function of roughness, slope, diameter of pipe, coarseness of material, percentage of material in the mixture, and specific gravity of the mixture.

When dealing with water alone the values of C in the Chezy formula were so involved that a simplified expression was urgently needed. About a generation ago the late Allen Hazen and the late Gardiner S. Williams, Members, Am. Soc. C. E., devised the following exponential formula for computing the friction due to the flow of water in pipe lines. The nomenclature used is the same as that in Equation (6):

$$V = C\,R^{0.63}\,S^{0.54}\,0.001^{-0.04} \qquad (9)$$

A slide-rule was devised for the convenient and rapid solution of Equation (9), and tables and diagrams have been prepared and published in handbooks and elsewhere. The writer uses this method for computing the losses of head in pipe lines. Mr. Howard states that, for water only, the exponential formulas are to be preferred; but for mixtures of sand and water—a more complicated condition—he uses the Darcy formula.

The normal problem confronting the dredge designer or operator is to determine the loss of head due to a given velocity when the other items of the problem have been determined or assumed. The author calls attention to the difficulties encountered in attempting to devise an exponential equation or equations that would give reliable results.

In Fig. 6 Mr. Howard has plotted certain data, and it is believed that an extension of this graphic method may result in a very useful diagram. If existing information is plotted now, the diagrams will be of immediate use to designers and operators. The diagrams will also indicate the nature of the information that should be secured by additional investigations in order to increase the sum total of knowledge on the subject.

In Fig. 10 the writer has plotted certain fairly reliable information with respect to the friction losses due to the flow of various concentrations of various kinds of materials, at various velocities, in a 4-in. pipe. Some adjustments of the basic data have been necessary. The curve for water only has been based on the value, $C = 140$, in the Williams-Hazen formula. This conforms fairly well with the author's observation that $f = 0.0206$ when the velocity was 5.4, and $f = 0.0164$ when the velocity was 11.2.

Curve (1), 15% loess, was plotted from data supplied by the author. The effective size (10% of the material is finer than this size) was taken from a diagram also furnished by Mr. Howard. Curve (2), 15% sand, was obtained from data published by John A. Vogelson,[13] M. Am. Soc. C. E. The suspended material was described as bar sand, with an effective size of 0.26 mm. The average of the runs used gave the percentage of sand as 15.97, and it was assumed that for 15% of sand the loss of head due to the presence of the sand would be proportional to the percentage of solids present, or $\frac{15}{15.97}$ times the observed loss.

Curves (3), 15%, 20%, and 25% sand, were computed from the data presented in Table 1 of the paper, the curves being then extended to indicate the rise in loss of head as the blocking-off points were approached. The blocking-off points were obtained from a smooth curve plotted as already explained, Curve (4), 15% sand, was plotted from data published by Mr. Vogelson[14] adjusted in the manner described for Curve (2), 15% sand. The analysis of the sand was as given by Mr. Vogelson.[15] The data for Curves (5), 15%, 20%, and 25% gravel, were taken from Table 1 of the paper and reduced by the foregoing method.

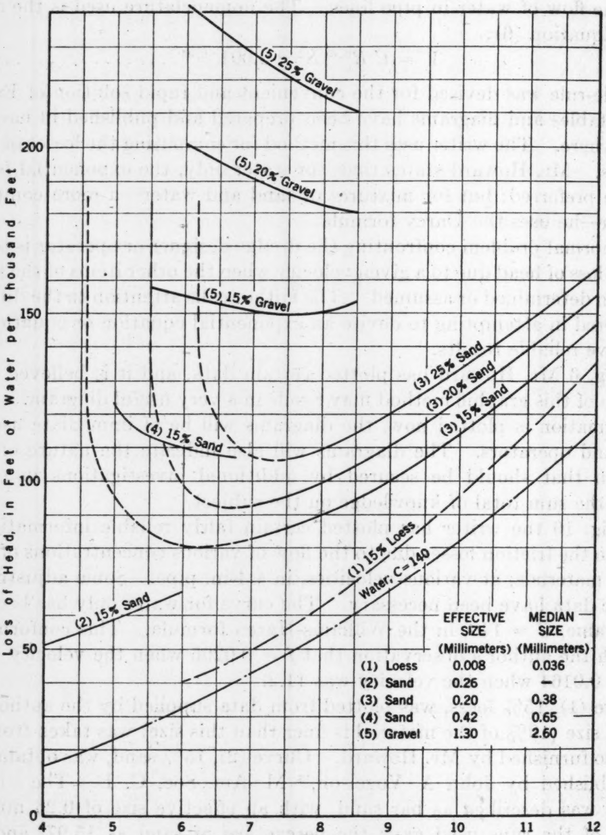

FIG. 10.—FRICTION IN A FOUR-INCH PIPE; MIXTURES OF SILT, SAND, GRAVEL, AND WATER

These are the only tests on 4-in. pipe that have come to the writer's attention, in which sufficient data have been published to make it possible to include them in the diagram, which is now sufficiently complete to warrant certain conclusions. Other data with reference to other pipe diameters might be cited to confirm the conclusions qualitatively although they have not been in sufficient detail to warrant the construction of special diagrams for those sizes.

---

[14] *Transactions*, Am. Soc. C. E., Vol. LVII (1906), p. 396.
[15] *Loc. cit.*, p. 395.

The following conclusions may be drawn as a result of the study of Fig. 10:

(*a*) For each variety and each percentage of sand, there is a blocking-off velocity below which the pipe clogs and the flow is shut off. The heavier the percentage of sand, or the coarser the material, the higher will be the blocking-off velocity.

(*b*) With a fixed percentage of a given material the loss of head decreases as the velocity increases from the blocking-off velocity to some point where the total friction is a minimum. The velocity corresponding to the minimum value of the friction loss increases with increase in the percentage of material and with the coarseness of the material.

(*c*) For velocities higher than those corresponding to the lowest friction losses, the loss-of-head curves approach the curve for water only for a certain distance, and then become substantially parallel to that curve. (Curve (1), 15% loess, and other data not published herein, indicate that with very high velocities the loss-of-head curves diverge from the water curve).

(*d*) A study of the curves and the effective sizes of the materials indicates that the effective size may not be a suitable measure of the coarseness of the material transported. This appears reasonable as the effective size is determined by the finest 10% of the material. The curves show that the effect of 15% gravel is much greater than that of 25% sand; or, in other words, that a small proportion of coarse material may have a greater effect that a large proportion of fine material. It may develop that a better index will be the size of opening in a sieve on which 25% of the coarsest material would be retained.

In practical dredging operations the muds and silts are well distributed throughout the entire cross-section of the pipe line whereas the sands and gravels concentrate near the bottom. Attention is particularly invited to the author's lucid description of the manner in which the material was moved through the transparent sections of the pipe during the experiments reported. These observations made on the 4-in. model are believed to apply qualitatively to the full-sized dredge pipes. For best results in practical dredging operations, the type of flow should be as indicated in Curves (3), 15%, 20%, and 25% sand, with velocities of 8.0 ft per sec, or more. For loess the velocities may be 6.0 ft, or less; and for gravel they should exceed 8.5 ft by an undetermined margin.

In an effort to find a practical working formula to be used in dredge design, the writer, in 1915,[16] suggested the following:

$$h = h_w + h_s = h_w + A\,N \text{ ....} (10)$$

in which (in the notation of the paper): h = the total loss of head due to the flow of a mixture of sand and water per 1 000 ft of pipe line; h_w = the loss due to the flow of water only at the same velocity; h_s = the excess loss due to the presence of the sand; A = a factor depending upon the character of the sand and the diameter of the pipe line; and, N = the percentage of sand present in the mixture.

---

[16] *Professional Memoirs*, Corps of Engrs., U. S. Army, March–April, 1915.

This formula puts into algebraic form a rule suggested by Miss Blatch[17] for determining the loss of head at the "economical velocity" and the rule given by Mr. Hazen[18] for transporting sand in 3-in. to 6-in. pipes. For conditions of flow corresponding to the best dredging range (velocities of 8 ft per sec to 12 ft per sec, in Fig. 10), the values in Table 4(*a*), for the terms in Equation (10) may be taken from Fig. 10, or computed. The mean value of *A* (Column (5) Table 4(*a*)) is 2.14. If this value is assumed as correct and if the losses of head are computed by Equation (10), the comparison between the computed and observed values will be as given in Table 4(*b*).

TABLE 4.—VALUES OF TERMS IN EQUATION (10)

Mean velocity, V, in feet per second	Percentage of sand, N	(*a*) FOR CONDITIONS OF FLOW CORRESPONDING TO BEST DREDGING RANGE				(*b*) COMPARISON OF COMPUTED AND OBSERVED VALUES				
		Total loss, h	Loss, h_w, due to water flow	Loss, h_s, due to sand	Factor A	Loss, h_w, due to water flow	Loss, h_s (=2.14 N), due to sand	Total Loss, h		Percentage error
								Computed	Observed	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
8	25	109	54	55	2.20	54.0	53.5	107.5	109.0	−1
	15	90	54	36	2.40	54.0	32.1	86.1	90.0	−4
10	25	133	82	51	2.04	82.0	53.5	135.5	133.0	+2
	15	114	82	32	2.13	82.0	32.1	114.1	114.0	0
12	25	163	115	48	1.92	115.0	53.5	168.5	163.0	+3
	15	147	115	32	2.13	115.0	32.1	147.1	147.0	0

The relatively small errors that would result, in this model test, from the assumption that, within the range simulating practical dredging velocities, the value of A is dependent solely upon the character of the material and the diameter of the pipe line, are most encouraging. It is hoped that additional data for testing this method will become available, and that, if the method is found to have merit, the working values for *A* will be established.

Practical dredging velocities have increased greatly in recent years due to the development of better machinery and other equipment. Fig. 10 shows how higher velocities make it possible to transport greater percentages of sand. In a 24-in. pipe line a velocity of 24 ft should be within the range of modern equipment and should be at the call of the crew whenever the need for it arises. Lower velocities would be adequate for pipe lines of smaller diameters. In a 1-in. brass pipe a velocity of 5 ft per sec was shown by Miss Blatch to be ample for sand having a median diameter of about 0.63 mm. In a 3-in. pipe with sand having a median diameter of about 0.65 mm, Mr. Vogelson found that a velocity of 8.5 was sufficient; and, with the same sand in a 4-in. pipe a velocity of 7.0 ft per sec was inadequate. Precise observational data for full-sized dredge pipes are not available and, as stated by the author, they are probably not obtainable.

---

[17] *Transactions*, Am. Soc. C. E., Vol. LVII (1906), p. 400.

[18] American Civil Engineers' Pocket Book, 1912 Edition, p. 935.

With respect to the diameter of the pipe lines it is known that, for the small sizes, the values of A vary rapidly with the diameter. It is doubtful, however, whether the variation on this account for dredge pipes of 12 to 34 in. in diameter are large. A comparison of Miss Blatch's experiment with a 1-in. brass pipe and Mr. Vogelson's experiment with a 3-in. pipe gives the following:

Description	One-inch brass pipe	Three-inch iron pipe
Suitable velocity, V, in feet per second	5.0	8.5
Head Losses in Feet:		
h	280	141
h_w	100	87
h_s	180	54
Percentage of sand	17.78	17.78
Factor A	10.10	3.04

The best available information is to the effect that, with similar sand, the values of A for pipe lines 12 in. to 34 in. in diameter would be between 1.0 and 1.5.

With respect to the effect of coarseness of the sand upon the values of A, the writer knows of no better information than that shown in Fig. 10, for 4-in. pipes. For full-sized dredge pipes the values are relatively small and the range of values is correspondingly small, provided always that the velocities are greater than those for the minimum friction losses on the head-velocity curves.

As long as a dredge can pick up a full load for its pipe line the most economical velocity will be the maximum obtainable with the equipment. An increase in velocity results in the transportation of a larger volume of mixture and the percentage of solids in the mixture may also be increased. The increase in power required to produce the extra velocity will cost much less than the value of the increase in pay work.

This paper is a valuable and timely contribution to the subject. If it encourages the publication of additional data and promotes a better understanding of the problem, future experimental work can be aimed at the solution of the remaining essential problems and progress in the direction of the final solution will be greatly facilitated.

David L. Neuman,[19] M. Am. Soc. C. E. (by letter).—The definition of "economical velocity" quoted, but not used, by Mr. Howard is of little value in dredge operation. The definition given is that (see "The Economical Velocity for Sand Transportation") "velocity at which any given volume of sand per hour can be transported through a given length of pipe with the least expenditure of power per unit volume of sand transported * * *." Such "economical velocity" will not result in minimum unit total costs. Fuel costs are a minor part of the total costs of dredging operations. For forty-five pipe-line, cutter-type, hydraulic dredges, varying in size from 12 in. to 30 in., the average fuel costs for 1937 was 13.3%; the average for 12-in. dredges was 8.3%; 20-in. dredges, 11.2%; and, 28-in. dredges, 17 per cent. Generally, minimum unit costs are obtained with maximum output per pumping hour.

---

[19] Maj., Corps of Engrs., U. S. Army, Grosse Pointe Village, Mich.

For many materials there is a rather narrow range of velocities in which maximum output is obtained. In a few instances it has been observed that a change of average velocity of 1.5 ft per sec, above or below the velocity producing the maximum output, would reduce the output as much as 40 per cent. This change in output is due to the change of velocity in the suction pipe. In soft or light material, especially, a small change in suction velocity may strongly effect the output. Theoretical considerations indicate that such results could be expected. The "economical velocity," as previously defined, would fall below the range producing maximum output, and the fuel savings through operation at the "economical velocity" would not offset the reduction in output caused by it. However, within the range of velocities producing maximum outputs fuel economy may be important. Many dredge-masters operate under the theory that maximum output is obtained with maximum obtainable discharge velocities. Frequently, outputs with existing dredges can be increased materially by decreasing the discharge velocities.

The discharge velocities must be sufficiently high to carry off, without danger of blocking the line, all the material that can be picked up on the suction side of the pump. Such velocities should be of Mr. Howard's third type of flow in which material is moving over the entire cross-sectional area of the discharge line. Average discharge-line loadings vary from about 12% to 20%; for short periods of seconds duration, loadings as great as 50% solids occur. The values are apparent percentages, which include the water in the voids for the material in place on the bottom. Indications are that for average loading in sand the third type of flow is obtained for values of velocity greater than 15 ft per sec in a 12-in. line, and greater than 19 ft per sec for a 24-in. line. In a 20-in. discharge line, it has been noted that even at a velocity of 22 ft per sec the line could be loaded so heavily with sand that some of the material could be heard moving along the bottom of the pipe. Table 1(*a*), for sand in a 4-in. line, indicates that at 12 ft per sec the loss of head, in feet of mixture, between 10% and 30% solids, was not increased by an increase of percentage of solids. Pipe-line blocking, even in coarse material, including boulders with mean diameters up to about 70% of the pipe diameter, can be avoided for the most part by the use of sufficiently higher discharge velocities. Velocities of 21 ft per sec for a 12-in. line to 30 ft per sec for a 30-in. line are suggested. In dredge design for increased higher discharge velocities, the suction diameter must be correspondingly increased to avoid the reduction of the picking up power of the suction line through too high suction velocity. Practical experience first indicated the need of small suction velocities with relatively high discharge velocities, and dredge design in recent years has followed the trend of increasingly larger suction diameters compared to discharge diameter with increased pump power for the higher discharge velocities. Apparently, minimum suction velocities have been taken at from 12 ft per sec to 14 ft per sec. It is believed that suction velocities might be safely reduced to 8 ft per sec and the output increased by such reduction.

The results of Mr. Howard's investigation could be used effectively if comparative results were obtainable for large size pipe such as that used for dredge discharge lines. Dependable and accurate gages permitting a continuous record of discharge velocities and percentage of solids passing through the discharge line have been developed and used since 1937 in connection with dredging operations. With the use of such gages in dredging operations results similar to those published by Mr. Howard are obtainable. With such gages installed on a dredge the range of discharge velocities producing maximum output and minimum unit costs can be determined on the site of the work, during actual dredging operation, without interference with such operation.

A most worth while investigation pertaining to obtaining increased output and decreased unit costs in hydraulic dredging can be secured through investigation of the action around the suction-mouth opening and in the suction pipe itself. Such investigation might well include the determination of favorable suction velocities for picking up various materials, head losses in the suction line, effective design of the suction-mouth opening, and the relation of suction-line vacuum and velocities to picking up and transporting ability. Such studies can best be performed in the laboratory where visual observation of suction-line action is possible.

MORROUGH P. O'BRIEN,[20] M. AM. SOC. C. E., AND R. G. FOLSOM,[21] ESQ. (by letter).—The writers have published[22] a paper on the transportation of sand in pipe lines, which presented experimental results on a number of sands. They have correlated these results with previously published data on materials ranging in specific gravity from 2.6 to 3.5 and median diameters from 0.0005 to 0.067 in. As this paper[22] draws conclusions which are in conflict with those of the author, a summary, supplemented by certain information not previously published, may be of interest.

The experimental equipment used by the writers was similar to that shown in Fig. 1 and about the same accuracy could be obtained with it. Nominal sizes for wrought-steel pipe were 2 in. and 3 in. The specific gravity of the mixture was determined by weighing measured volumes. The head loss was measured by differential manometers and expressed in feet of the flowing mixture. Runs were made with clear water before and after the series of runs with each sand. The test pipes were horizontal. During some of the runs, a 3-ft length of glass tubing of proper diameter was inserted in the pipe lines.

Conclusions pertinent to a discussion of Mr. Howard's paper were:

(1) At a given sand concentration, there was a certain velocity below which sand tended to accumulate on the bottom of the pipe, ultimately causing clogging if the flow conditions were maintained constant;

(2) Above this critical velocity, the head loss of the sand-water mixture, expressed in feet of the mixture, was found to be the same as for fresh water within the limits of accuracy of the experimental data; and,

(3) The ratio of the pressure drop (horizontal line) for clear water and sand-water mixtures was equal to the ratio of specific gravities.

[22] "The Transportation of Sand in Pipelines," *Univ. of California Publications in Engineering*, Vol. 3, No. 7, November 12, 1937, pp. 343–384.

If these conclusions are valid, they simplify the computation of head losses with sand-water mixtures because it is necessary only to know the friction loss in the same pipe with clear water. In order to test this relationship, the writers recomputed the published data of Miss Blatch,[23] W. B. Gregory,[24] N. Mikumo,[25] E. J. Dent,[26] M. Am. Soc. C. E., and unpublished data on a few dredges operated by the United States Engineer Department. It was found that all the laboratory experiments agreed with the conclusion that, above a certain critical velocity, the head loss for a sand-water mixture, expressed in feet of the mixture, was the same as the head loss for water in the same pipe. Below this critical velocity, the head loss remained very nearly constant as the apparent velocity, $\frac{Q}{A}$, was decreased. This phenomenon, observed first in the Blatch tests, was ascribed by the writers to accumulation of sand in the pipe to an extent which approximately held the true velocity constant. This conclusion was confirmed by the trend of the curves obtained by Professor Gregory on slurry so fine that it did not settle fast enough to reach equilibrium between runs.

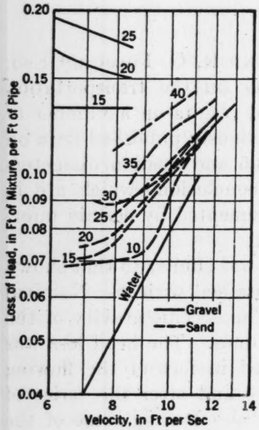

Fig. 11.—Combination of Figs. 6(*a*) and 6(*b*), Expressed in Terms of Head Loss, in Feet of Mixture per Foot of Pipe.

Fig. 11 shows all the author's data on sand and gravel mixtures and the friction curve for clear water. The trend of these curves is toward the "water" line; unfortunately, the experiments were not carried to sufficiently high velocities to determine whether the curves for mixtures are asymptotic. The data are in general agreement with the writers' conclusions previously mentioned.

There are a number of points in the paper under discussion which require clarification. In Fig. 4, the maximum velocity shown is approximately 6.3 ft per sec, whereas on the following page the velocity of flow is given as 8.88 ft per sec. The exact diameter of the test pipe before and after the experiments is not stated. Although the head loss with clear water is shown in Figs. 6(*a*) and 6(*b*), the friction loss or friction coefficient is not specified. The "water" curves in Figs. 6(*a*) and 6(*b*) appear to differ slightly, raising a question as to whether this difference represents a real change in the pipe characteristic.

In introducing Equation (1), the author states that "when applied to water, exponential pipe formulas are more accurate than the Darcy formula

* * *." There may be a question of convenience involved, but certainly not of accuracy if Equation (1) is properly used with *f* as an experimentally determined function of the Reynolds number.

Fig. 7, showing the lines of head loss as a function of velocity, is misleading. The points show a tendency (pronounced in the case of 30% of solids) to break away from the line, and extrapolation as shown is not justifiable.

The distribution of sand concentration shown in Fig. 4 may be explained at least quantitatively in terms of mechanism of turbulent flow. Field measurements by Colonel Dent[26] gave the same type of sediment distribution curve as Fig. 5. A conclusion drawn from this theory is that the settling velocity of the material being transported is its most important characteristic; the sieve analysis, specific gravity, percentage of voids, and other measurable characteristics are important only in so far as they provide a means of estimating the settling velocity. To complete the data, it is desirable that the author measure the mean settling velocity of the pea gravel and Pearl River sand used in his experiments. Using approximate methods based on the sieve analysis, the writers have estimated the mean settling velocities of the author's materials as: Sand, 0.19 ft per sec; and pea gravel, 0.76 ft per sec.

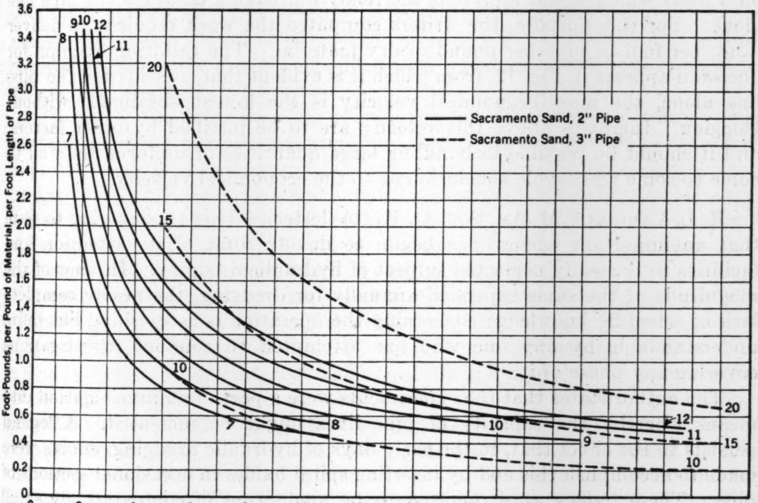

FIG. 12

One of the obstacles to an understanding of the mechanism of sand transportation in pipe lines has been the failure to separate driving unit, pump, and pipe line in field tests. As a consequence, scores of over-all tests of dredges have been made without yielding data of general significance. A similar situation appears to exist in determining the economical operating conditions. The pipe line can, and should, be regarded as a separate unit requiring a certain power input in order to operate at a specified velocity and concentration. To this power may be added the loss in the pump, driving unit, transformers, and all other elements of the energy system, and the total power utilization may then be converted to terms of cost. To this cost, computed for a range of practicable operating conditions, must be added all over-head, interest, and other charges to obtain the total cost of the project. To be sure, some of these items are difficult to estimate, but they do not tend to make the pipe-line problem any less definite, as the author implies. As a matter of fact, the true situation seems to be that no one is really concerned about the economical velocity. Avoidance of clogging in non-uniform materials, specified dates for completion of the work, the fixed notions of operators, and other practical considerations control pipe-line velocities; but these do not make it impossible to come to some conclusion as to what the most economical velocity would be if one is interested in knowing it.

The experiments conducted by the writers were initiated for the purpose of comparing the difficulty of dredging in three locations. Representative samples were secured for the tests and the laboratory results had to be compared on a basis which would represent the relative dredging costs for the pipe line alone. For this purpose, the writers computed the work required to deliver sand, per foot of pipe per pound of dry material. The resulting diagram for one sand appears in Fig. 12, from which it is evident that, considering the pipe line alone, the most economical velocity is the lowest obtainable without clogging. Increases above this velocity are to be justified by other factors, and it should be possible in handling large quantities of uniform material to come to some reasonable conclusion as to the economical velocity.

R. L. VAUGHN,[27] M. AM. SOC. C. E. (by letter).—It is encouraging to note that an important agency has begun to devote some of its attention and facilities to the sadly neglected subject of hydraulic dredging. In view of the magnitude of the sums expended annually for dredging, the nearly complete lack of scientific knowledge concerning the operation is astonishing but quite understandable by any one who has attempted to conduct investigations covering any phase of it.

The author states that the experiments were a part of an investigation into means whereby the capacity of pipe lines might be increased. A legend persists to the effect that, in the early days of hydraulic dredging, efforts were made to accomplish this end by inserting spiral baffles in occasional sections of pipe. These baffles were reported to be angle-irons of comparatively small size, but of considerable length (probably about 16 ft). Also, at one time, it was contended that spiral riveted pipe had an advantage in this respect. The idea, of course, was to impart a whirling motion to the mixture and thus prevent undesirable concentrations in the bottom of the pipe. Spiral pipe failed to substantiate its claims to superiority and baffles did not survive the initial trials.

The "apparent percentage of solids" is a convenient factor in dredging work since it furnishes a ready means by which the output of a dredger in operation may be calculated. It is a very treacherous factor for use when estimating the performance of a dredger in advance and is likely to give a misleading idea of the true properties of any mixture to which it is applied. Two banks of sand, of identical mechanical grading, may have substantially different percentages of voids, depending upon the circumstances under which they were deposited. Obviously, if 1 cu yd of sand from each bank, in turn, is mixed with 9 cu yd of water, the result in both cases will be a mixture containing "10% of solids"; and yet the two mixtures may be substantially different. Similarly, the entire series of clays, from fluid muds to hard clays, may be regarded, for dredging purposes, as simply fine-grained matter mixed with more or less water. Any one of them, by the admixture of the requisite quantity of water, and with sufficient agitation, can be reduced to a fluid mud. If a soft mud bank is excavated by a dredger and pumped at the rate of 4 cu yd of water to each yard of mud, the only trouble with the mixture containing "20% solids" will be to prevent its escape from the fill into some navigable waterway where it is certain to irritate the United States District Engineer. On the other hand, if a stiff clay bank is excavated and pumped at the rate of 4 yd of water to one of clay, the resulting mixture of "20% solids" will irritate a number of people. Use of this and other redundant or misleading phrases, such as "bulk density" and "bulk specific gravity," should be avoided in engineering work. In the present case it is not clear whether the percentage was computed on the basis of a volume of sand with the voids filled with water, or on the basis of an equal volume with the voids filled by air.

[27] Cons. Engr., San Francisco, Calif.

Efforts to correlate observed phenomena on a false basis account for at least some of the troubles encountered by investigators attempting research on a subject which is at best most difficult and confusing. Two properties of any pumpable mixture are of primary importance; one is the weight, and the other is the grading of the particles. Another important factor, not solely a property of the mixture, is the ratio between the diameter of the larger particles and the diameter of the pipe through which the mixture is forced.

It has generally been assumed that a mixture of water and solid particles will act exactly as a liquid of equal weight, and that all the fundamental laws of hydraulics may be applied to it. This can be true only as long as the mixture is a uniform one; when material begins to settle in a pipe there is no longer one mixture but an infinite series of them grading from top to bottom; and when material begins to roll or drag along the pipe the area of the flowing stream is reduced, and most of the hydraulic laws no longer are valid. There is thought to be a critical velocity which will keep the mixture uniform, but no one has discovered any formula for it. Both the weight of the mixture and the grading of the particles seem to be involved. Where the larger particles are balls of clay or porous objects having a unit weight materially different from that of the solid matter in the mixture, the density of the particles will also be an important factor.

The effect of the grading is well known. It is notoriously easier to pump a mud than a sand, and there is a marked difference in pumping sands depending upon whether they are fine or coarse. On the other hand, any dredging man will comment feelingly upon the difficulty of pumping clay balls. However, no quantitative data on this subject have been presented to the profession.

The importance of the size of the pipe has received more recognition in recent years. Formerly, it was thought that so long as a velocity above the critical one was maintained the output would be directly proportional to the weight of mixture, velocity, and area of pipe. With the advent of high-powered dredgers of large size it has developed that, all things considered, clay can be pumped through large pipe lines much more effectively than through small ones. The fact is known but not the fundamental laws governing it. Something other than mere friction loss of head seems to be involved.

Eventually, probably, some property of mixtures analogous to the viscosity of liquids will be evolved; and, probably also, something resembling the "effective size" and "uniformity coefficient" which have been evolved in connection with studies of the flow of water through soil. Whoever discovers these properties will have the privilege of naming them. The soil mechanics investigators have invented an imposing glossary to describe newly discovered and hitherto unsuspected properties of earths. Dredging specialists certainly have the right also to a jargon of their own whenever they can discover properties to which to apply the words. It is suggested that appropriate names for some of the new units would be "Gilmores," "von Schmidts," and "McMullins," in honor of some of the early pioneers. Surviving old timers would probably be unanimously in favor of naming a particularly objectionable characteristic after the late Alonzo P. Bowers.

The author mentions difficulties arising from the variable nature of the mixture in a dredger pipe line. In part, these difficulties are due to practical considerations involved in the operation of the dredger. Clear water must be pumped while "fleeting." When digging, the material will cave down on top of the suction at an irregular rate so that it is impossible even to approximate a constant feed. Some factor other than those due to operating conditions also seems to be involved. Occasions have arisen in which it was possible to introduce reasonably uniform material into a pipe line by controlled means at a constant rate. In some instances efforts were made to determine the loss of head. It was found impossible to maintain a constant mixture and, at the same time, attain any value approaching the maximum capacity of the set-up. Results of observations were about as satisfactory as have been all other observations concerning the hydraulic performance of an hydraulic dredger.[28]

It is unfortunate that a motor was not used in the present experiments rather than a gas engine, since with an electric drive it would have been possible to determine the power used at various times. The author states that the velocity was first set at about 5 ft per sec and a solid concentration introduced. What happened to the velocity, and what steps if any were taken to bring it back to 5 ft per sec? How was the velocity determined in the first place?

After a state of equilibrium had been attained and some observations made, the velocity was increased but the rate of discharge of solids was kept constant. Again, how was the velocity measured, and how was the mixture controlled? From an inspection of Fig. 1 it is not clear how the procedure described could have been followed readily. On the other hand, with this arrangement it would have been easy to make a mixture of any predetermined consistency, and keep it circulating at any desired speed. After observations had been taken on one constant mixture at all velocities desired another mixture could have been made and observations again taken at predetermined velocities.

---

[28] *Engineering News-Record*, June 16, 1921, p. 1035.

It was only necessary to make tests on gravel at velocities ranging from 5.5 to 8.5 ft per sec, which emphasizes the importance of the relation between size of particles and size of pipe. On a dredging scale it would be impossible to obtain satisfactory results when pumping this gravel at a velocity as low as 8.5 ft per sec.

It is not clear where the data pertaining to solid matter discharged, percentage of solids, and velocity of flow in pipes, came from (see heading, "Method of Transporting the Material: Sand"). The information is supplied in connection with Fig. 4 which shows a maximum velocity of only slightly more than 6 ft per sec, while the tabulated velocity is 8.88 ft per sec.

Mention is made of difficulties in determining the velocity distribution shown in Fig. 4. Evidently, the sampling device was used as a Pitot tube. Were the several pressure readings in each case reduced to feet of head of the particular mixture which existed at each of the several points where observations were taken? A small reaction plate could be calibrated and substituted for the Pitot tube, thus avoiding clogging troubles. Such a disk must have a considerable size relative to the size of the particles in the mixture, and in this case could not have been used for gravel as it would necessarily have been about as big as the pipe.

The author used feet of mixture rather than feet of water in the preparation of Tables 1 and 2. It is to be regretted that he did not follow this same correct procedure when drawing Fig. 6. He states that where material settled to the bottom of the pipe there was a greater loss of head than for slightly higher velocities because of increased pressures caused by the constrictions. The explanation is incorrect. Where constrictions occurred the local velocity, perforce, rose because the same volume was passing all points, and it was this increase in velocity which caused the increased loss of head. The pressure had nothing to do with it; and, in fact, there must have been a local drop in pressure at the constricted points, or the case for Bernoulli's theorem and all Venturi meters is weak indeed.

Changes observed through the windows are advanced as explaining the variations in values of f in Table 1. Aside from the rolling and jerking, what changes, if any, were observed? The rolling and jerking were reported to occur at rather definite velocities, whereas the variations in Table 1 appear to be quite regular throughout the entire range of velocities.

The opinion is expressed in the paper that it is impossible to obtain a formula for loss of head that is applicable to any but a specific gradation of material. In other words a separate formula is needed for each batch of dirt. The writer does not agree. He believes that when research has disclosed the inter-relationship between the essential variables, weight of mixture, gradation, specific gravity of particles, diameter of pipe, and velocity, a satisfactory formula can be written containing factors that reflect the influence of each variable.

A general criticism of the paper and of nearly all other investigations of the kind is that the true nature of the problem is not recognized. The essential study is that of the flow of a mixture. When solid particles settle to the bottom of the pipe and begin to jump, slide, and roll, they no longer follow the law of flow of mixtures; nor does the water entrapped within them follow that law. The problem with respect to such accumulations is: What can a certain flowing mixture do in the matter of shoving material along the bottom of the pipe? The mixture itself is whatever remains actually flowing. The essential factors are the weight, gradation, velocity, etc., of the flowing stream. It is no more correct to include the rolling and dragging material than it would be to conduct dynamometer tests on a ship's model in a tank while the model was dragging an anchor behind it, and the results are about equally valuable.

From the accounts given, it is suspected that in these tests, at least at the lower velocities, the velocity was considered to be the result of dividing the total discharge by the area of the pipe, and that the percentage of solids was determined from the volume of sand and water in the sampling tank. Reflection will show that whatever sand was scraped into the tank had nothing to do with the quality of the mixture, and that the velocity should be that of whatever was flowing, not some quantity derived by including materials that did not flow and areas through which flow did not occur. It cannot be expected that the fundamental laws governing flow will be disclosed when these non-relevant items are reflected in the observations.

Figs. 7 and 8 appear much more concordant and orderly than most plottings of data of the kind, and it is possible that the attempt to evolve a formula was abandoned without due consideration.

Recently tests of transportation of sands in 2-in. and 3-in. pipes were conducted by Morrough P. O'Brien, M. Am. Soc. C. E., and Mr. R. G. Folsom, at the University of California.[29] Those tests form a valuable supplement to those described by the author.

The California experimenters point out that Stoke's law does not apply to particles of sizes frequently encountered in dredging practice, but, nevertheless, they find that, for sands, so long as the critical velocity is exceeded, the flow is a turbulent one, and therefore, as was to be expected from the laws of turbulent flow, the viscosity or density of the mixture is not a factor in the problem. They also found that, above the critical velocity, the loss of head expressed in feet of mixture was the same as it would be for clear water. All the available evidence, including that contained in the paper, tends to sustain these findings and the conclusion is important even if it is at variance with ideas previously held in dredging circles.

Messrs. O'Brien and Folsom also observed the performance of the pump and found that the pressure developed was not directly proportional to the weight of the mixture pumped. This is entirely in accord with the fact that Stoke's law does not apply to such mixtures. The general theory of centrifugal pumps indicates that the head developed with any liquid is constant, that is, that the pressure for any given discharge will be directly proportional to the weight of the liquid. When dealing with dredger pumps it has generally been assumed that the mixture would behave as a true liquid. In a previous discussion the writer questioned this assumption.[30]

---

[29] Univ. of California Publications in Engineering, Vol. 3, No. 7, pp. 343–384.

Under actual operating conditions on a dredger it is difficult if not impossible to maintain a constant mixture for a time sufficient to permit a determination of the weight of the mixture, the head developed, the power input, and the discharge. The observations at the University of California are the only ones known by the writer to bear directly on this problem. If the author should make any further tests it is to be hoped that he may be able to include the performance of the pump in his observations.

Messrs. O'Brien and Folsom concluded that the most important single property of a mixture was the settling velocity of the particles composing it. A turbulent flow is one consisting of a combination of linear flow and cross-flow. It is suggested that further investigation might reveal a relation between average velocity, cross-velocity, and diameter of pipe line, and further that it might be found that whenever the transverse velocity exceeded the settling velocity the flow became fully turbulent. In this manner it might become possible to predict, for any given pipe, the minimum velocity which would maintain turbulent flow for a mixture containing clay balls, cobbles, shells, and similar particles, the settling velocity of which could be determined.

As far as the writer is aware no observations have been taken of settling velocities of particles in any liquid but water. It might be found that the velocity of a clay ball, for instance, falling through a liquid mud was much lower than that falling through water, and, consequently, that the critical velocity for a mixture of mud and clay was less than that for clay alone.

Possibly the problem of transporting material in pipe lines is not one involving turbulent flow only. Experience suggests that the greatest rate of output may be attained when some of the material is carried in suspension, while, at the same time, some is also moved by being dragged or rolled along the bottom. This would involve two different types of flow in the same pipe at the same time and obstacles in the way of arriving at any laws governing the situation are obvious. If a mixed flow is the one which will transport the most material, reported troubles in determining the maximum or economic weight of the mixture would be explained since flow under this condition must be somewhat unstable.

All the author's formal conclusions and his remarks under the headings, "The Economical Velocity for Sand Transportation" and "Transferability of Experimental Results," are exceptionally sound and pertinent. They are endorsed unreservedly as far as they go.

The economical velocity for a dredger involves factors not mentioned by the author. Fig. 13 shows tests conducted with Columbia River sand on the dredgers, *Wahkiakum* and *Multnomah*. These are sister machines, with both suction pipe and discharge pipe 24 in. in diameter. It will be noted that as the pipe-line velocity increased, not only did the percentage of solids fall, but so did the output of the dredger, until the highest attainable velocity was approached. The answer to this seeming paradox lies in the dredger—not in the pipe line nor in the flowing stream. By increasing the power used, the pressure and velocity can be raised to almost any reasonable extent; velocities of 35 ft per sec and working pressures of 125 lb are not unknown. On the suction side of the pump, however, the pressure is absolutely limited to 1 atmosphere. Nothing can be done to increase it, for which reason, in theory, the proper place for the pump is out on the ladder immediately behind the cutter.

---

[30] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 651.

This pressure of 1 atmosphere must do several things. It must overcome entrance losses, and friction losses, and must create velocity head. If the center of the pump is above the water-line it must lift all water pumped this additional distance. Most important, the excavated material must be lifted and fed into the pump. If a disproportionate fraction of the total available pressure is used to accomplish the former objects, little or nothing remains available to bring in pay dirt.

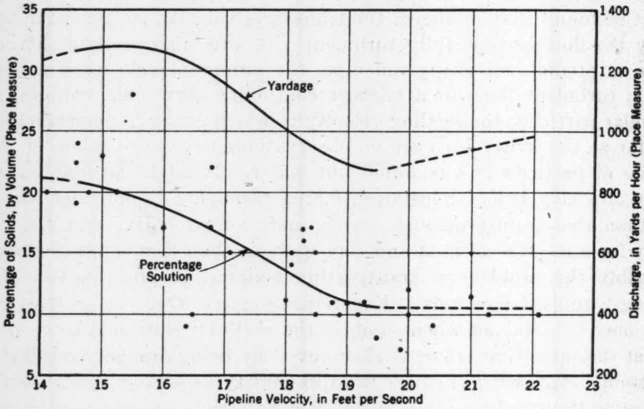

FIG. 13

The illustration is no isolated instance. The fact has been confirmed many times. On some electric dredgers the speed of the pump, and consequently the pipe-line velocity, may be varied at will, within rather wide limits. Power consumption is immediately visual through indicating watt-meters. By trial it has been found frequently that lowering the velocity would actually increase the output materially, not only when pumping sand but when pumping clay.

As far as the dredge operator is concerned, the economic velocity is the one that will get out the most material. The unit cost for "wear and tear" is about constant; unit costs for labor, over-head, interest, depreciation, etc., are inversely proportional to the output; and, although the unit cost for power may be slightly higher for the higher outputs the increase, if any, is seldom enough to offset the other gains. Of course, this is not the true problem of the economical velocity in the pipe line and the dredge operator spends his spare time wondering what would happen if the diameter of the suction pipe or the diameter of the discharge pipe were increased. Eventually he builds a new machine in which the size of both is increased. After a comparatively brief operating interval it is decided that more power is needed, which is duly installed, and the operator is right back where he started except that he has a larger dredge.

Finally, the announced object of the experiments was to devise means whereby the flow of mixtures in pipes might be improved. Results of early-day experiments indicated that any device inserted in the pipe would constitute an obstruction causing more harm than good. Experience indicates that boosters are more effective than dredge pumps. For illustration, a combination of a 1 500-hp dredger pump and a 500-hp booster out in the line is likely to do better work than a 2 000-hp pump on the dredger without a booster. The reason the booster is effective is thought to be that it stirs the mixture.

Boosters are heavy machines, expensive to install; they require considerable labor for attendance, and are anything but mobile pieces of equipment. Their use is avoided wherever possible. In special instances, especially where electric power is readily available, it might prove feasible to fit a few sections of shore pipe with small motor-driven centrifugal pumps arranged to draw practically clear water from the top of the pipe line and inject it into the bottom again under considerable velocity. Devices of this kind, located about a half mile apart along a long pipe line, might be found to be surprisingly effective and to require much less power than one would be inclined to suppose. The writer has not heard of anything of the kind, but it would not cost much to try the idea.

M. P. DUREPAIRE,[31] ESQ. (by letter).—In certain respects, sand transportation in dredge pipes is still in a crude, empirical state. A better understanding of the basic laws governing this technique is needed because great sums of money are spent each year in pumping sand mixtures through pipes in conditions which are often far from the best possible.

The paper by Mr. Howard is a welcome contribution to current knowledge on the subject in the wealth of experimental data and engineering remarks contained in it. Experiments with the same problem have been in process for several years in France, and a brief summary of the unpublished results thus far obtained should constitute a constructive discussion of Mr. Howard's paper. Tests on the flow of sand mixtures through water pipes were started in 1935, under the direction of engineers in charge of Nantes harbor. These tests were conducted in a steel pipe of 52 mm, inside diameter (2.05 in.). Loire River sand was used, screened so that the maximum grain size was 0.3 mm (0.012 in.). The volume of the voids was 43% and the specific gravity was 1.945 kg per cu decimeter (121 lb per cu ft).

The test layout was a closed circulating system operated with a centrifugal pump of adequate design. Two glass sections were provided for observing the conditions prevailing during each run, and the following conclusions were reached:

(1) When all the load is in suspension and within the range of concentration encountered in the experiments (to 40%), the loss of head (measured in feet

---

[31] Ingénieur des Ponts et Chaussées, Nantes, France.

of the mixture under test) was the same as with clean water, regardless of the sand concentration, except at the stage when deposition is impending.

(2) For each concentration, a critical velocity was found corresponding essentially to that in which deposition occurs in a stage of decreasing velocities, this critical velocity being approximately that at which the minimum loss of head occurs. With the grain size used in the Nantes experiments, the loss of head was never found to be less than that with clear water.

(3) It was concluded that, theoretically, jerking motion such as that described by Mr. Howard, and the well-known phenomenon of sudden blocking of the entire section, was a problem involving stability of flow conditions encountered with mixtures. This stability condition depends on the characteristics of the kinetic head. These phenomena can be avoided entirely by using a specially designed centrifugal pump. No jerking motion was observed in the glass sections of the Nantes experiments, whereas it seems impossible to avoid that type of motion using a gravity head such as that in the Howard experiments.

(4) The loss of head in the partial deposition phase appears to be a very complex phenomenon. It was found in the partial deposition phase that, for a constant concentration of sand, the loss of head is greater when the total discharge decreases. At the same time the height of deposited material increases. The deposit in a given run was of rather uniform depth because no jerking motion was taking place. The same depth could be obtained in a fairly wide range of discharge with different concentrations of the flowing mixture. It was found that, for a given constant depth of deposit, the loss of head varied as the square of the discharge, whatever the concentration.

(5) Within the duration of each run, the deposition phenomenon did not seem to be a reversible phenomenon; that is, it requires higher velocity to pick up material than the velocities which prevailed when the material was deposited.

This means that in the partial deposition phase, the loss of head for a given discharge and a given concentration may have a very different value compared with the condition prevailing in accelerating or decelerating the flow. In the phase under discussion, the phenomenon cannot then be represented by a single curve, but covers a zone. In undertaking to study this feature more closely, it is essential to use a well designed pump.

The foregoing conclusions were deduced from the laboratory experiments. As far as actual dredge lines in the field are concerned, the writer agrees with the general conclusions reached by Mr. Howard. However, although due regard must be given to all costs (such as running costs, amortization, etc.), the most important guides in designing new dredges and dredge lines are the results obtained on pipes in the laboratory, transporting material similar to that to be used in the field.

The economical velocity is practically the aforementioned critical velocity, and this must be obtained with as high a concentration as feasible. The minimum energy per unit of sand volume, obtained for each concentration when the mixture is flowing with a critical velocity, diminishes when concentration increases. This energy would reach a true minimum for high concentrations which would not be generally feasible with the technical equipment now available.

Common experience with dredge lines has shown that the most serious difficulty in running dredging equipment arises from the danger of sudden plugging of the line when pumping in the partial deposition phase. Such plugging is likely to occur not only in long lines pumping coarse material, but also in any length of pipe or size of material. This danger of plugging causes most dredge lines to be run at velocities that are far from economical; and until now the so-called economical velocity has been only of academic interest when the cost of re-starting flow in a plugged pipe was taken into account.

The fact that, with proper design, the pump can be given special characteristics that avoid the possibility of jerking and plugging is, then, of prime interest. Consider one of the older dredges in Nantes harbor. It has a main engine of 1 000 hp with a centrifugal pump of a type that could pump Loire River sand only for a distance of approximately 900 m to 1 000 m (2 950 to 3 300 ft), using a 580 mm (23 in.) pipe. At this distance, the sand volume pumped was limited to about 575 cu m (750 cu yd) per hr, under conditions in which sudden plugging was a real menace. The entire design of this dredge was made according to what is considered good normal practice.

In the new pumps, with the same engine, the pumping distance is now 1 800 m (5 900 ft) with the same pipe diameter. At this distance, the sand volume pumped is normally 1 100 cu m (1 440 cu yd) per hr, with the same grade of sand as previously used. The danger of sudden plugging is now practically eliminated.

Since the concentration of the mixture thus pumped was more than 25% (bulk volume), the efficiency of the pump was about 80 per cent. There was much less wear in these pumps than in the older ones.

In the same general research, the suction heads have been perfected so that higher concentrations can be pumped. This is of major interest when dealing with fine sand, which can then be pumped away easily. Such fine sand, especially when mixed with muddy silt, is not so easily picked up and carried in suspension because natural deposits are often quite compact. A special suction head was designed using the entire flow of water to disintegrate the soil, the energy being supplied by the pump itself. A great uniformity is obtained without the risk of plugging. Concentrations are greater than 20% when working in compacted sand of very high impermeability. The best dimension for the suction pipe has been derived for each condition.

The foregoing shows conclusively that the study of sand transportation in dredge pipes is most effective when theoretical knowledge of hydrodynamics and hydraulics is combined with experiments on small size test pipes. Although accurate measurements of the performance of big dredge lines in the field are difficult to obtain, such observations of field behavior and the interpretation of phenomena observed are essential.

The transportation of sand in pipes is a complex problem in the partial deposition phase. The flow condition depends largely for its stability on the characteristic of the kinetic head; and, although the flow conditions might be as described by Mr. Howard in certain pumps, the writer feels that, with a proper design, the flow condition could be much improved, and thus a genuine economical velocity could be used. As both the pump and the suction head must be able to produce the high concentration that the pump now is able to drive through the line, it seems difficult to study the behavior of the line alone.

Although the laws governing all these phenomena appear to be extremely complex, the results noted thus far are gratifying. The difficulty of the task is no reason for abandoning research. Even if the final goal is still far removed, it must be reached, step by step, and investigators are still working in a stage where great strides can be made.

A broad exchange of ideas between workers in this field will foster progress and Mr. Howard deserves credit for making his results available to the Engineering Profession.

Acknowledgment.—The researches conducted at Nantes, mentioned in this discussion, were formerly conducted by Mr. R. Siegfried, under Chief Engineer M. Notté, and later by the writer. Technical advice came from Messrs. Louis Bergeron and Paul Bergeron, who designed the pumps, and also supplied valuable technical advice.

PIERRE F. DANEL,[32] ASSOC. M. AM. SOC. C. E. (by letter).—Knowledge of turbulent flow has been much advanced in recent years, both through theory and experiment. Researches on sediment transportation in open channels that have been reported show encouraging results. Laws governing sediment transportation in pipes have much in common with those of open channels, and, as long as the basic differences are understood, much can be derived from one field to benefit the other. Among the most important differences is the effect that the free surface in open channels has in damping turbulence. This effect will create a very different distribution of time, average velocities, turbulence intensities, and sediment concentrations.

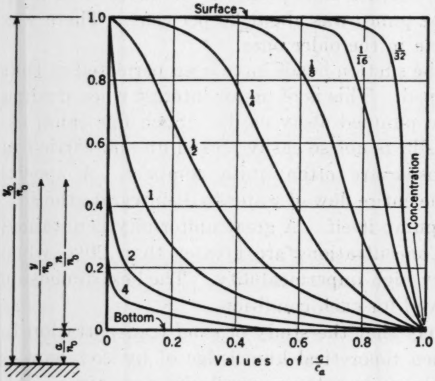

FIG. 14

Fig. 14 shows some distribution curves of different typical sediment concentrations, arranged according to their relative state of turbulence.[33] The effect of the free surface damping out turbulence is apparent as the concentrations diminish rapidly near the free surface.

Fig. 15 shows the approximate concentration distributions for a closed pipe. The bottom part of the curves is similar to that of open channel but the top is quite different. When all the sediment is in suspension in the pipe, and if the concentration distribution is fairly uniform (see Curve *A* or Curve *B*, Fig. 15), the loss of head in the depth of the mixture is the same as that of water (as reported by Miss Blatch,[2] Mr. Gregory,[34] and at Nantes, France). In this case, the conditions are nearly those of an homogeneous fluid.

---

[32] Research Engr., Neyret-Beylier Piccard Pictet; Director of Hydr. Laboratory, Ecole des Ingenieurs Hydrauliciens, Grenoble Univ., Grenoble, France.

[33] "Fluid Mechanics for Hydraulic Engineers," by Hunter Rouse, Assoc. M. Am. Soc. C. E., McGraw-Hill Book Co., New York, N. Y., 1938, p. 342.

When the mean velocity is decreased the concentration distribution will no longer be uniform and, at the same time, when deposition occurs, the concentration distribution curve is of a type similar to Curve *C* or Curve *D*, Fig. 15. When the maximum size of the particles is small enough, a curious phenomenon may occur, as it did in experiments reported by Mr. Gregory. The loss of head (in depth of mixture) in a limited range of velocities may be less than that of clear water. This may be explained as being due to the damping effect of density gradation on turbulence, just as the density variations with height cause that well-known calmness of the atmosphere at sunset. The atmosphere is fairly homogeneous, however, whereas the mixture is not. If the particles are coarse their continued falling through the fluid creates a turbulence of its own, and there is little likelihood that the density variation can reduce turbulence to the point where the loss of head is less than that of water. When, on the contrary, the maximum size is such that the free fall of the grains would occur in laminar conditions (that is, particles of less than 0.1 mm), it is quite possible to get a loss of head, less than that of clear water, in a very limited range. In the experiments conducted by Mr. Howard, the grain sizes are too large to permit such a phenomenon to occur, but that must not be taken as a general proof that its occurrence is impossible.

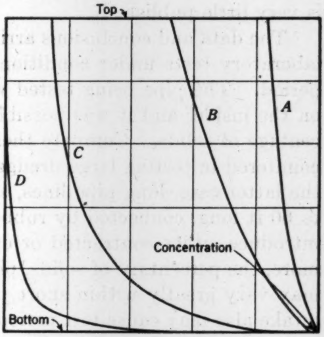

FIG. 15

In an open channel, the influence of a sudden deposition somewhere cannot be transmitted faster than surface waves, and the pressure changes involved are always small, whereas in closed pipes the pressure changes are transmitted at the velocity of sound in the pipe which is many times that of the speed of surface waves, and the pressure changes involved may be fairly great.

The jerky motion described by Mr. Howard, and the sudden plugging of the dredge pipe, do not have an exact parallel in open flumes, which shows that the comparison must not be extended too far. However, in mountain streams, mud flows of very high concentrations are stopped suddenly, sometimes in a manner that reminds one of the plugging of dredge pipes. In open channels only gravity flow is considered, whereas in closed pipe the kinetic head is generally produced by a pump, and flow conditions may vary considerably according to the pump characteristics, as accidental disturbances may or may not be smoothed out.

---

[34] *Mechanical Engineering*, June, 1927, p. 609.

The design of pumps giving a stable performance outside of the cavitation range is a great step toward economy in the transportation of sand in pipes because, not only can a greater quantity be pumped, but the wear is much less.

In connection with the construction of dams the writer has been engaged for sometime in laboratory tests by throwing stones in flowing water. The theory of S. Isbach[35] has been checked and its scope has been broadened considerably. The almost perfect check between theory and experiment is very encouraging and, for material that is sufficiently coarse, the possibility of solving the deposition problem of gravel transportation in dredge pipe is not remote.

H. S. GLADFELTER,[36] M. AM. SOC. C. E. (by letter).—Dredge engineers and others interested in the hydraulic transportation of solids will find this paper valuable because it furnishes information on a subject about which there is very little published.

The data and conclusions arrived at by the author have been obtained from laboratory tests under conditions that were controlled during the entire test period. The pipe being tested was straight, of uniform cross-section, smooth on the inside; and it was possible to control the velocity, grain size, and percentage of solids. Compare these almost ideal test conditions with those encountered in testing large dredges engaged in actual dredging operations. In the latter case, long pipe lines, seldom straight, are made up in sections 50 ft to 60 ft long, connected by rubber sleeves, ball joints or tapered joints, which introduce either contracted or expanded sections in the pipe lines. Furthermore, the percentage of solids, pipe-line velocity, and character of the material may vary greatly within short periods. The presence of trash in the system intake also may cause test periods to be interrupted. These conditions render any test to determine pipe-line characteristics very difficult and may account for the meagerness of published information on the subject.

During the three years, 1936, 1937, and 1938, the writer made a number of tests on 32-in. pipe-line dredges of the dust-pan type operated by the Memphis Engineer District on the Mississippi River, in the maintenance of its navigable channel. They included the determination of the carrying capacity of several types of pipe lines. The observations made during these tests were suggested by the author, and were generally similar to observations made on the 4-in. test pipe at the U. S. Waterways Experiment Station. A comparison by the author of the test results obtained in the laboratory with those obtained in the field on the 32-in. dredge should furnish valuable information.

In Fig. 4 the author shows the distribution of sand in the 4-in. test pipe. The distribution of sand in the 32-in. pipe tested is shown in Figs. 16(*a*) and 16(*b*). This condition was found to exist with pipe-line velocities of 14.78 and 21.85 ft per sec, respectively, and the observed percentage of solids under these conditions was 13.3 and 18.2, respectively. Examination of the distribution of sand in the two sections of pipe shows that the sand is transported in the manner described by the author as the first method. The writer has found that low pipe-line velocities will result in plugged pipe lines. The earlier dredges built by the Mississippi River Commission were operated at pipe-line velocities ranging from 13 to 18 ft per sec with resulting percentages of solids ranging from 10 to 15. When these dredges were operated at a high rate of advance, with increased percentage of solids pumped, frequent plugging of the pipe line resulted. In dredges now (1939) operated by the Memphis District, velocities of 25 to 26 ft per sec pumping water, and 23 to 25 ft per sec pumping solids, are obtained.

FIG. 16.—DISTRIBUTION OF SOLIDS IN 32-INCH PIPE

To improve the carrying capacity of pipe lines used for transporting heavy material the Memphis District installed rifles or vanes on the inside of the pipe line of one of the dredges of the district, and included tests of this type of pipe with tests of plain pipe. The effect of the rifles was to reduce the concentration of solids in the bottom of the pipe and prevent plugging that may occur at low pipe-line velocities. These rifles are shown in Fig. 17. The test of this type of pipe showed concentration of solids as in Figs. 16(*c*) and 16(*d*). These tests were made at the same pumping speeds obtained in tests that produced the concentrations of solids shown in Figs. 16(*a*) and 16(*b*). In this test the pipe-line velocities were 15.79 and 20.30 ft per sec, respectively, and the average percentage of solids was 18.1 and 24.7 respectively. This distribution of solids in the rifle-fitted pipe is more uniform than in the plain pipe, and is a result that may be expected in the third type of transportation of sand referred to by the author.

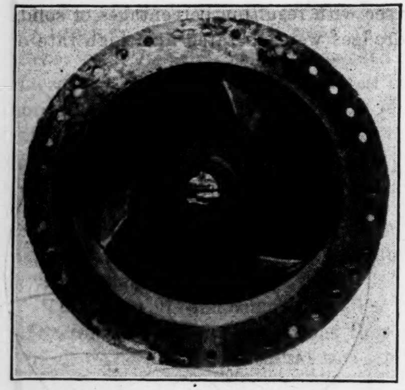

FIG. 17.—TYPICAL RIFLED PIPE

Mr. Howard has referred to the "economical velocity" for sand transportation, and gives four factors that must be balanced carefully for its determination. This procedure may be permissible when a new dredge is being designed. After its construction, however, the pipe-line velocity can be changed within limits by changing the speed of the prime mover or by changing the pump impeller. One condition which is not referred to by the author in determining the economical velocity and which would appeal to dredge operators is the cost of pipe-line and pumping equipment maintenance. When pumping a high percentage of solids containing abrasive material, the wear on the pipe line, pumps, etc., may be excessive at high velocities and it may be found more economical to operate at reduced velocities.

G. W. HOWARD,[37] JUN. AM. SOC. C. E. (by letter).—It is desired to emphasize the fact that the data presented were obtained in connection with an investigation which was concerned primarily with methods for increasing the capacity of pipe lines transporting solids. The tests in question did not stress flow through plain pipe and, therefore, are not as complete as in the case of a study of plain pipe alone. The primary purpose was the development of the design of rifling referred to by Mr. Gladfelter.

Certain features of the apparatus have caused some concern. The most important of these are the method of introducing material into the tank and the sampling apparatus. Fig. 18, a general view of the apparatus, shows: (*a*) The line into the upper tank through which the material from the sump was pumped, (*b*) the upper tank, (*c*) the test line, (*d*) the trough for diverting the discharge, (*e*) the volumetric basin, and (*f*) the scales. Fig. 19 presents details of the sampling tube. It should be noted that this equipment was not used as a Pitot tube, but was simply an arrangement for taking representative samples from definite locations in the cross-section. Velocities at these various

FIG. 19.—SAMPLING DEVICE

places were obtained volumetrically with this apparatus, the mixture being discharged into a standard graduate. As was originally stated, velocities determined in this manner were considered merely as weights "because it was not possible to obtain a satisfactory calibration of the sampling device." Average velocities in the pipe were greater than velocities obtained through the sampling device. The principal use of this sampling device was to determine solid concentrations at any given point in the cross-section. Average velocities in the test line were obtained by diverting the discharge from the test line into a volumetric basin and weighing the trapped sample. The velocity in the test line was controlled by means of a positive-action valve which was located just below the upper tank.

Of primary interest in the preparation of the paper was the gathering of data available on the subject of sand transportation in pipe lines. The additions made by Messrs. Brown, Durepaire, and Gladfelter tend to further this purpose. Messrs. Montgomery and Vaughn have shown that values of f are sensitive to changes in area; thereby, they clarified a misleading explanation of a phenomenon to which insufficient space had been given. Thanks are due to these gentlemen for clearing this point.

Colonel Dent prefers the Chézy formula to that of Darcy. This seems to be a matter of personal preference, because the value of C would of necessity become also a function of "coarseness of material, percentage of material in the mixture, and specific gravity of the mixture," which is objectionable to Colonel Dent but unavoidable under the existing circumstances.

Equation (10), suggested by Colonel Dent, is of particular interest. It is gratifying to find that the data which were presented were of value in providing an additional check on his formula. A compilation of Factor A would be of considerable value to all those engaged in the study of transportation of material in pipe lines.

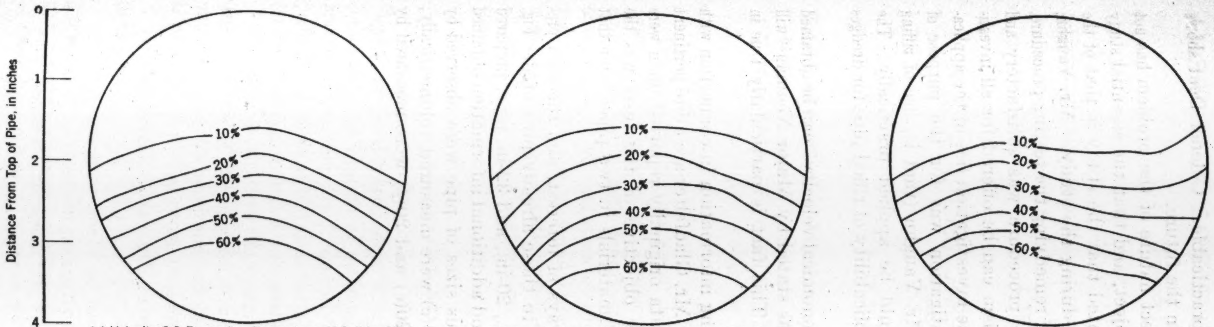
Conclusions presented by Professors O'Brien and Folsom should not be considered at variance with those advanced in the original paper, because of the different range of velocities used for the two series of tests (velocities for the California tests were greater than for the writer's tests). Certain differences which seem apparent, possibly, may be reconciled as follows:

(1) The California tests indicated that, for a given sand concentration, there was a velocity below which sand tended to accumulate on the bottom of the pipe, ultimately causing the pipe to block off, if flow conditions were constant. The writer's tests on 4-in. pipe indicated that material was carried along the bottom of the pipe in the lower velocity range; but, if a certain concentration was exceeded for a given velocity, the pipe would block off.

(2) The California tests indicated that the head loss of the sand-water mixture was the same as for fresh water. The writer's tests on 4-in. pipe indicated that the value of the friction factor decreased with increases in velocity. Indications, from Table 1, are that the values of the friction factor tended to approach those for clear water.

Mr. Vaughn objects to "the apparent percentage of solids." This factor is admitted to have its limitations, but is one that is used with satisfaction in dredging practice on the Mississippi River. Furthermore, it is satisfactory for use in comparing flow characteristics of identical mixtures through two different types of pipe, as was the case for the study in question.

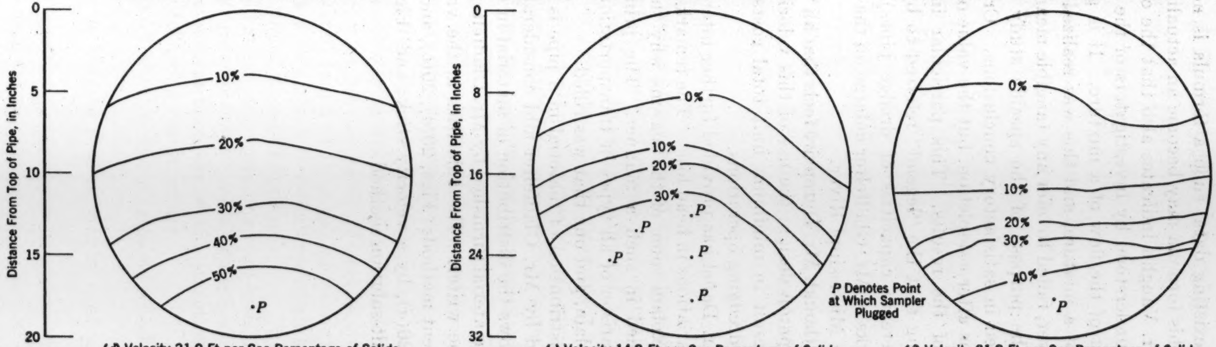
The implication that a general formula is impossible was not intended, as was interpreted by Mr. Vaughn. It was intended, however, to state that,



(*a*) Velocity, 6.0 Ft per Sec; Percentage of Solids, 13.3; Sand Settled on Bottom Diameter of Pipe, 4 In.

(*b*) Velocity, 7.3, Ft per Sec; Percentage of Solids, 15.0; Sand Settled on Bottom Diameter of Pipe, 4 In.

(*c*) Velocity, 8.9 Ft per Sec; Percentage of Solids, 14.4; All Sand in Motion; Diameter of Pipe, 4 In.



(*d*) Velocity, 21.0 Ft per Sec; Percentage of Solids, Unknown; Diameter of Pipe, 20 In.

(*e*) Velocity, 14.8 Ft per Sec; Percentage of Solids, 13.3; Diameter of Pipe, 32 In.

(*f*) Velocity, 21.8 Ft per Sec; Percentage of Solids, 18.2; Diameter of Pipe, 32 In.

FIG. 20.—DISTRIBUTION OF SOLIDS IN PLAIN PIPE

from existing data, such a formula is not practicable. Colonel Dent shows that this formula may become an actuality in the future.

Mr. Vaughn indicates also that the correct nature of the problem has not been understood by investigators of the subject, and that the essential study is that of the flow of a mixture. It is granted that the study is that of the flow of a mixture, and this was realized all during the study. Mr. Vaughn, however, failed to offer any tangible means of remedying the testing procedure. For the purpose of the specific study the procedure was satisfactory and resulted in satisfactory conclusions. Criticism can be offered for all investigations after completion, but the value of the investigation lies in the application of the results. This particular investigation was for the purpose of proving that the "legend" referred to by Mr. Vaughn (that is, use of rifling to increase capacities of dredge pipes) could be applied practically. The remarks of Mr. Gladfelter enlarge on the applicability of rifled pipe for dredges in the Mississippi River.

Although Mr. Durepaire feels that an "economical velocity" can be obtained with pump design, the use of this velocity as stated by Major Neuman "will not result in minimum unit total costs." This fact is particularly true in large dredging operations.

Mr. Danel has provided further interesting information in connection with the variations in head loss. The remarks by Mr. Gladfelter are quite pertinent and explain some of the reasons why the data originally reported upon were obtained in such a manner. The primary objective of the tests was the comparison of all types of transportation of materials in two pipes: One that was plain, and one that was rifled.

Distribution of material in a pipe is always of interest, and the data presented by Mr. Gladfelter add considerably to those already presented. Fig. 20 shows the distribution of material in 4-in., 20-in., and 32-in. pipe, prepared from material furnished by Mr. Gladfelter, and additional information obtained by the writer. The velocities in the various sizes of pipe were observed by different methods: Figs. 20(*a*), 20(*b*), and 20(*c*) were measured volumetrically; Fig. 20(*d*), by a velocity stick; and, Figs. 20(*e*) and 20(*f*) were measured by the salt-solution method.

PRINCIPLES APPLYING TO HIGHWAY ROAD-BEDS

BY IRA B. MULLIS,[1] ESQ.

WITH DISCUSSION BY MESSRS. A. F. GREAVES-WALKER, H. Z. SCHOFIELD, W. H. CAMPEN, BERNARD E. GRAY, W. J. TURNBULL, BERT MYERS, E. NEIL W. LANE, AND IRA B. MULLIS.

SYNOPSIS

The purpose of this paper is to present, for criticism and discussion, a process of reasoning and development in road-bed design and construction rather than to set forth definite rules and data; to apply the laws of mechanics of materials to the solution of road-bed problems; and to stimulate research and thought in the rational design of road-beds. The mechanical properties of typical earthy formations are discussed with reference to their suitability for road-bed use. Construction methods and experience are presented and discussed.

ESSENTIAL STRUCTURAL REQUIREMENTS

With respect to the design, construction, and use of any structure, certain physical properties are required. These properties and their inter-relationships constitute that branch of science known as Mechanics of Materials. Other branches of science are frequently required to aid in the explanation or interpretation of certain physical facts; but with respect to structures of all kinds, the mechanics of materials furnishes a direct means of approach.

The first essential to the design of all structures, including road-beds, is the determination of the specific structural requirements, such as type and magnitude of load to be supported by the several members of the structure. A satisfactory road-bed must possess the following requirements:

(*a*) Compressive strength in excess of that of the maximum wheel load to be used;

(*b*) Effective pore space so limited in volume that it cannot receive sufficient water to produce plasticity;

NOTE.—Published in September, 1938, *Proceedings*.

[1] Assoc. Highway Engr., U. S. Bureau of Public Roads, Omaha, Nebr.

(*c*) Water content so restricted in quantity as to cause the road-bed to remain an elastic solid; and

(*d*) Surface protection against the destructive forces of traffic, weather, and erosion.

To satisfy the foregoing requirements, both designer and builder must possess adequate knowledge of the structural requirements of road-beds and must be familiar with the mechanical properties of the available materials to be utilized.

GASES

Every one knows that matter exists in three states: Gases, liquids, and solids. Gases belong to that form of matter which is elastic and tends to expand indefinitely. The gas that affects road-beds most is air. Its chief characteristic, as it relates to road-beds, is that of expansibility. If a pint of liquid is poured into a quart bottle, it does not expand and fill the bottle. In contrast, an inflated pneumatic tire is punctured, and the escaping air expands and occupies considerably more room than it had before.

During the period of road-bed construction the engineer is concerned with the elimination of air from earthy materials. This removal is essential before earth particles can unite. After a road-bed has been completed the presence of a limited quantity of air in its pores restricts the quantity of water that these pores may receive. In case of freezing, the air is either compressed or removed, and room is thereby furnished for the expansion of the freezing water within the pores without disrupting the solid mass. Thus, it will be seen that a limited air content in the fine pores of a road-bed is an element of safety. For this reason the better grades of sand-clay gravel roads do not fail under frost action.

LIQUIDS

A liquid is a body of matter, such as water, which offers resistance to any change in size, but none to change of form. The only liquid to be considered herein is water which, when pure, has a specific gravity or density of 1.00 gram per cu cm at 4° C. Within the scope of this paper this value is satisfactory for all atmospheric temperatures above the freezing point. Pure ice, at the freezing point, has a density of 0.9175. With the density of water considered as unity, therefore, it will be seen that 1 unit-volume of pure water, upon freezing, becomes 1.08+ units, an expansion of 8 per cent. However, under field conditions, this expansion (including entrapped air) is generally considered to be about 10 per cent. When freezing water is rigidly confined, its force is enormously destructive. The only known method of avoiding this destruction to road-beds is that of restricting the quantity of water that may enter them.

The forces exerted by water are both gravitational and molecular. The gravitational force is too well known to require more than mention. The molecular forces, because of their finite scope and the conditions under which they act, frequently evade interpretation. They include adhesion, cohesion, and chemical affinity. Discussion of how these forces act is beyond the scope of this paper, but knowledge of the conditions under which they apply is essential.

As a constituent of road-beds, water is essential at all times. Its importance as a means of removing air during the period of construction has already been stressed; but the removal of air is not enough. Particles must be cemented together, if all their potential strength is to be utilized. On the other hand, the excessive use of water is to be avoided; otherwise, a weak and excessively porous or fissured structure is obtained. "Spare the water and increase the weight of the roller" is generally a safe maxim when compacting earth, but the presence of excessive volumes of air in the compacted mass should not be tolerated.

SOLIDS

A solid body is one which offers resistance to any force that tends to change either its form or its size. The ultimate particles of a solid are considered as being bound together by some kind of intermolecular force which causes them to resist forces tending to separate them.

The theory of solids includes the concept of continuity of matter, but, in a strict sense, this is never true. Even atoms contain much open space. Although steel is an excellent example of an elastic solid, it possesses a crystalline structure. When crystal size in metals or non-metals is reduced and the crystals are more closely arranged, strength is increased. Moreover, it has been shown that certain metal surfaces can be ground and polished to planes so perfectly fitted as to bring them within range of molecular forces sufficient to offer considerable resistance to their separation.

Bodies of earth within the definition of that of a solid are to be found occurring, both naturally and artificially, everywhere. It is this state of aggregation of earth particles that is most desirable for road-beds.

To solidify masses of earth, the constituent particles and molecules must be united. This process involves the removal of air, the development of cementing properties, and close molecular arrangement of all constituent particles. In this process, water is essential both as an aid in the removal of air and also in the preparation of the clay molecules for the uniting process. Another essential is adequate pressure. With the aid of water and pressure, the molecules are brought into that state of aggregation in which intermolecular force-functioning becomes possible. The mass may now be considered as having been "welded" into a solid body.[2] Upon completion of the welding process it may be considered as a malleable solid possessing considerable compressive strength.

Of course, small masses of clay particles may also be united into strong bodies by the simple process of thorough wetting and mixing, followed by controlled drying. This method may be termed "aqueous fusion" and is somewhat analogous to the fusion of metal scraps into a solid body. Under certain conditions, such as that of constructing a sand-clay mat, the aqueous fusion process may be used advantageously in highway work; but its use should be restricted to granular or thin masses where adequate drying is possible during the process of construction. This method should not be attempted in heavy clays where the development of shrinkage fissures will certainly cause trouble, unless they are solidly filled during the period of construction.

With respect to the manner in which solids resist forces, hardness, brittleness, elasticity, and plasticity may be mentioned as being important mechanical properties applying to road-beds.

---

[2] "A Treatise on Metamorphism," by C. R. Van Hise, *Monograph 47*, U. S. Geological Survey, 1904.

Hardness, in the broadest sense, is that property of any material that causes it to resist deformation or abrasion by external forces. This characteristic depends, first, upon the nature of the chemical substances it contains; and, second, upon the state of molecular aggregation. The quantity of water present in rocks and minerals is an important factor of hardness. Hydrous minerals are invariably softer than those of a similar character except that they contain less water; for example, quartz is harder than opal. The only chemical difference between quartz and opal is the presence of water in the opal in varying percentages ranging from about 2 to 13.[3] The softness of wet brick, wet stone, and other non-ferrous materials in contrast to the same materials in the dry state are too well known to require discussion. It may be mentioned, however, that clays are hardest when in the densest and dryest condition; and, of course, they soften and also weaken in proportion to increases of porosity and water content.

Brittleness is characteristic of materials having little or no plasticity. Such materials have a very low elastic limit and this is poorly defined. Failure of this class of materials under stress, therefore, is sudden and generally without warning. Dry clays are characteristically brittle and such materials are not well adapted to road use. Moreover, dry particles are easily sheared, form dust, and, therefore, produce traffic hazards.

Elasticity is that property of solids which causes them to recover or tend to recover change of form or size upon removal of the deforming force. Within the elastic limit, stress and strain are proportional; but when the pressure exceeds that of the elastic limit of a given material, plastic flow has begun.

One of the essentials of any traveled way, whether it be path or road, is that of elasticity. The road must be able to resist wheel loads adequately and also to recover after their passage. The elastic limit of the road-bed must be adequate for all loads under expected conditions of weather.

Inasmuch as bone-dry clays are characteristically brittle and wet ones plastic, obviously there must be a state of moisture at which a given clay may be caused to attain its maximum elasticity. The methods for developing elasticity will be discussed later.

Plasticity may be described as follows: A body is said to be plastic when it has the ability to change its shape, even to a marked extent, without rupture. A perfectly plastic material is one on which an applied load, however small, produces a permanent deformation. Plasticity in the wide sense of the word, according to the New Century Dictionary, means the possession of a structure weak enough to yield to an influence, but strong enough not to yield all at once. The word is defined by Alfred B. Searle[4] as "that property of a material by means of which it may be deformed or changed in shape and yet retain that shape when the deforming force is removed." Heinrich Ries[5] defines plasticity as "the property which many bodies possess of changing form under pressure, without rupturing, which form they retain when the pressure ceases, it being understood that the amount of pressure required and the degree of deformation possible will vary with the material." The late Mansfield Merriman,[6] M. Am. Soc. C. E., defined a material as plastic when it has no elasticity, so that the smallest forces cause permanent deformation.

---

[3] "Textbook on Mineralogy," by E. S. Dana, Fourth Edition, 1932.

[4] "The Chemistry and Physics of Clay and Other Ceramic Materials," by Alfred B. Searle, Second Edition, p. 274.

[5] "Clays, Their Occurrence, Properties and Uses," by Heinrich Ries, Second Edition, p. 119.

Work done by Bennett H. Levenson and verified by Charles Terzaghi,[7] M. Am. Soc. C. E., showed that pressures as small as 5.6 lb per sq in. were sufficient to produce plastic deformation in all wet bodies of earth tested (including both fragile and tough clays). His experiments also showed that plastic deformation occurred at equal moisture contents in duplicate bodies of earth regardless of the magnitude of the loads applied. The loads applied were 5.6, 12.0, 16.0, and 32.0 lb per sq in., respectively. In all cases, the bodies were free to deform in one or more directions.

Yield Point Due to Water Content.—The moisture content at which earth and other wet ceramic bodies change from the elastic to the plastic state is known as the yield point due to water content. By this definition it will be seen that earth containing water, equivalent to that of its yield point, will behave as a plastic body. All unconfined plastic bodies not only deform when loaded, but continue to do so without any increase in the applied load. This yield point of plastic clay bodies under load may be said to be analogous to the yield point of a loaded mass of red-hot steel which is also plastic. Both metallurgists[8] and structural engineers[9] recognize the effect of applied heat in the reduction of the strength of metals. Gustav Tammann states, "With increasing temperature the tensile strength of metals decreases at first slowly, then rapidly so that at a red heat most metals have only a very small tensile strength." The law of "plastic yield" governs in both cases. Moreover, it is evident to the physicist that in the processes of drying wet clay and of cooling hot steel, both first lose their plastic properties and then pass into states of elasticity. It must also be remembered that beyond certain limits of dryness of the clay or of the coldness of the steel the elastic properties disappear and the bodies are then said to be brittle. The effect of water content on the several states of coherent earth is illustrated in Fig. 1. By substituting the words, "Temperature increasing," instead of the words, "Water content increasing," on the *X*-axis of the diagram, the effect of temperature on the strength of metals may be illustrated.

By definition of Ries,[5] the yield point of plastic clay is equivalent to Albert Atterberg's "lower plastic limit," [10] which is restricted by the point of rupture or rolling-out limit. However, Atterberg's method of determination is made in the reverse order, that is, by a process of moisture decrease instead of that of moisture increase. A comparison of the essential rupture feature in the Atterberg test with other definitions of plasticity reveals the harmony of the definitions of all investigators of plasticity. Furthermore, the yield point due to water content of fine sands and silts was found by Levenson[7] to approximate

75% of Atterberg's "lower liquid limit" value. Moreover, in many types of plastic earth the relationship between these limits is such that 75% of the lower liquid limit value frequently approximates the lower plastic limit value, but important exceptions to this relationship are to be found.

Fig. 1.—Illustration of Effect of Water Content on the Several Mechanical Properties of Earths

Granular Masses

Material in a granular state is exemplified by sand and gravel deposits, which are characterized by their limited compressibility and the ease with which they receive and lose water. Owing to the surface tension of water, moist sand under traffic is more stable than dry sand.

The ease with which pores or voids in masses of coarse sand and gravel receive the discharge water is too well known to require discussion. In contrast to this, the pores in masses of very fine sand and silt are noted for retaining much of the water so readily received. Assuming a usual bulk density of sand and gravel to be 1.70 and that of silt to be 1.36 and both having an absolute density of 2.65, the former will have a pore space of 35.8% and the latter, 48.7 per cent. To fill the voids in the mass of sand and gravel with water would require a quantity equivalent to 21.0% of their dry weight; however, probably less than 5% of it would be retained. To fill the voids in the mass of silt would require a quantity of water equivalent to 35.8% of its dry weight and most of this water would be retained against gravitational drainage. The water retained in the mass of sand or gravel would be an asset in aiding traffic over it, but the water retained in the mass of silt would convert it into a quagmire.

LOOSE, AMORPHOUS, PLATE-LIKE, FIBROUS, AND CELLULAR MATTER

Loose material, regardless of other attendant structural properties, should have no place in a road-bed. Pore space is always large in loose materials and when the individual openings are so small that the force of surface tension is greater than that of gravity, water is removed only through evaporation.

Dry Clay.—The brittle properties of consolidated masses of dry clay have already been discussed under the heading, "Solids." Loose masses of dry clay are composed of particles or chunks containing much air. In this state, the mass can be neither compacted nor welded into a solid. Dry masses of earth utilized in the formation of road-beds should be expected to contain many air-filled cavities which are likely to contribute to future saturation and settlement. Dry earth should be utilized in road-bed construction only for blending or conditioning wet earth so as to obtain little variation of moisture throughout the structure.

Although loose deposits of moist clay or well-graded mixtures of sand and clay have possibilities for being converted into road-beds of considerable strength and durability, even these should have no place in a road-bed until they have been well compacted. Masses of earth particles which do not conform to the definition of a solid as given by the physicist cannot function as a part of a satisfactory road-bed.

Wet Clay.—Whether it is in a plastic or fluid condition, wet clay is generally in a state of expansion; it has very little supporting capacity and, therefore, should not be utilized. When it must be placed in road-beds, it should be used sparingly and distributed so that excess water will become absorbed by contiguous dryer layers of earth during the period of road-bed construction.

Road-beds constructed of wet earth shrink upon drying and, therefore, lead to the development of shrinkage fissures. These fissures become water-filled during rainy seasons and thereby contribute in large measure to the never ending cycle of excessive moisture changes and their attendant instability.

Plate-Like Particles.—Plate-like fragments or particles belong to one of three general classes: Brittle, elastic, or flexible matter. Of these, brittle, plate-like matter, such as spalls of rock, may best be utilized only when sandwiched between layers of moist, compact earth so that bond is provided for these incoherent fragments.

Cellular Matter.—Another type of brittle matter is that of diatomaceous or radiolarian earth. Both these types consist of shells of siliceous matter mixed with greater or less quantities of earth. These shells or frustules have various shapes, but all are more or less cylindrical, cup-like, cellular, or rod-like in form and have many openings which give the particles a kind of lace-like appearance. The pore space within, and also between, these minute shells forming the mass is enormous, and all pores are so small as to resist gravitational drainage when filled with water. Due to the fragility of the particles and also to the enormity of the pore space, neither diatomaceous nor radiolarian earth is satisfactory for use in road-beds.

Volcanic ash deposit contains enormous pore space also. Its utilization in the formation of road-beds, therefore, should be restricted to the minimum. In no case should it be placed in the upper part of the road-bed nor on road-bed slopes where it may be subjected to erosion.

Micaceous Earth.—The only minerals that possess marked elasticity so that they spring back when deformed, are the micas. These mica flakes when associated with common earth tend to produce a fluffy mass. Even the presence of small quantities of mica flakes increases mass porosity. Although the individual flakes possess considerable elasticity, the mass cannot be considered an elastic solid. Due to lack of stiffness and other structural weaknesses, bodies of micaceous earth may be utilized only when better material is not available. However, if this material is utilized, the upper 2 ft or more of the road-bed must be formed of select earth if maintenance troubles are to be averted.

Peat.—Spongy cellulose matter such as peat, humus, leaves, and straw has an absolute density of about 1.5. The absolute density values obtained for peat deposits from five localities along the Atlantic Coast and one from the State of Washington as determined by Messrs. I. C. Feustel and H. G. Byers[11] ranged from 1.105 to 2.161, the mean value being 1.533. Abnormally high density values are obviously indicative of mineral contamination to a considerable extent. In further substantiation of the absolute density of cellulose matter being about 1.5, the research personnel of the United States Forest Products Laboratory states that the absolute density of the actual wood substance of all structural timbers is about 1.54.[12]

The bulk density values of dry peat as given by Messrs. E. K. Soper and C. C. Osbon[13] are as follows: Turfy peat, 0.11 to 0.26; fibrous peat, 0.24 to 0.67; earth peat, 0.41 to 0.90; and, pitchy peat, 0.62 to 1.03. The bulk density values of dry peat from localities already mentioned, as determined by Messrs. Feustel and Byers,[11] ranged from 0.06 to 1.21, the mean value being 0.53. The effect of the presence of considerable quantities of mineral matter is again apparent in its influence upon density increase. A tabulation of thirty-three commercial woods tested in the U. S. Forest Products Laboratory shows bulk density values, when corrected to a 0% moisture content, ranging from 0.29 to 0.65, with a mean value of 0.44. It becomes apparent, therefore, that the only essential difference between the structural properties of timber and those of peat consists of difference in porosity and bond between fibers in the respective materials.

Due to its enormous pore space and also to its marked affinity for holding water,[11] [12] deposits of peat are to be avoided as road locations when possible.

MEASUREMENTS OF THE PROPERTIES OF ROAD-BED MATERIALS

The design of road-beds, like that of other structures, must be based necessarily on the mechanical properties of the materials to be utilized. The usual location survey must be supplemented by a materials and profile survey which includes soundings, collection of cores and samples of all strata, and, finally, the measurements of the mechanical properties of the specimens and samples collected. For obvious reasons no designing should be started until all design data, including materials tests, are complete.

DENSITY

The term, density, is used in two senses: (1) Absolute density, for expressing the weight per unit volume of constituent particles of a solid or mass, exclusive of voids; and (2) bulk density for expressing the weight per unit volume of mass, including voids. In both cases, the numerical value of density is expressed in grams per cubic centimeter.

Bulk density is frequently expressed in the English system as weight in pounds per cubic foot, but the metric system is to be preferred for these measurements since absolute density is always expressed in that system. Furthermore, when bulk density is expressed in the English system, the two terms, absolute density and bulk density, must be expressed in the same system before pore space can be computed. Moreover, the metric system is better adapted to scientific work since it does not involve the awkward volumes and weights of the English system.

Absolute Density.—The term, "absolute density," is frequently called absolute or true specific gravity and in geology, "mineral specific gravity." In all cases it signifies the ratio of weight of a given volume of dry matter, unaffected by porosity, to the weight of an equal volume of distilled water. Absolute density may be determined by any one of several well-known methods, all of which require precise weight and absolute volume measurement of the matter being investigated.

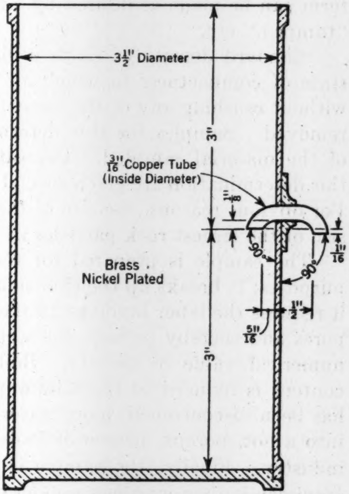

FIG. 2.—OVERFLOW VOLUMETER

Bulk Density.—The term, "bulk density," signifies the unit weight, in grams per cubic centimeter, of dry matter being investigated, including its contained pore or void space. It is synonymous to the term, "bulk specific gravity," and also to the term, "rock specific gravity," frequently used by geologists. Bulk density measurements may be performed by any one of several well-known methods, but the use of kerosene in the overflow volumeter (shown in Fig. 2) is recommended for volumetric measurements in the laboratory. This volumeter was designed by Mr. L. L. Marsh of the Kansas State Highway Commission. It is of the siphon type, dripless in performance, and capable of giving precise results on specimens of considerable size. The balance should be accurate to 0.1 gram for laboratory work and to 0.5 gram for field work.

Volumetric measurements of earth in cut and also in fill are readily made by the use of a 4-in. post-hole auger for obtaining the sample, and its volume may be obtained by filling the hole with common S.A.E. 30 oil or dry, screened sand, of known density, from the spout of a pot containing a known weight of the material utilized. A table for converting the weight of these materials into metric volumes is a recommended convenience, based on the formula,

$$\text{Bulk density} = \frac{\text{Dry weight, in grams}}{\text{Bulk volume of mass, in cubic centimeters}} \quad \ldots\ldots (1)$$

Subdivision of Bulk Density.—Inasmuch as bulk density measurements are utilized in three distinct states or conditions of compactness, it becomes necessary to restrict its meaning to suit its precise application to a given problem. The term, bulk density, therefore, has been subdivided into three brief expressions: "Cut density," "fill density," and "standard density."

The term, "cut density," will be applied to all bulk density measurements made on specimens of undisturbed rock or earth taken from "cut," "borrow," or other sources from which "fill" material is to be obtained.

Fill density will be the term applied to all bulk density measurements made on specimens taken from "fill," after the fill material has been placed in its final position or in a given state of compactness. Further restrictions of this term can be made as desired by adding a limiting adjective, such as "rolled," "tamped," etc.

Standard density of earth utilized in road work may be defined as that state of compactness in which all pores have been reduced to the minimum without crushing any of the constituent particles, and all water has then been removed. Samples for this determination obviously must be representative of the material sampled. Deposits containing rock fragments too large for this determination are given special consideration through other measurements. For obvious reasons, the size of the sample taken must be proportional to the size of the largest rock particles in it.

The sample is prepared for test by vigorous boiling. This serves three purposes: It breaks up the clod structure without crushing the rock fragments; it reduces the labor involved to the minimum; and, it removes all air from the pores and thereby permits the wet mass to dry and shrink to a reproducible numerical value of density. Boiling should be continued until the water content is reduced to the minimum boiling limit. When the boiling process has been discontinued, more water may be removed by pouring the wet mass into a hot, porous, plaster-of-Paris mold similar to those used in the pottery industry. Finally, the sample is dried in an oven. The dried and cooled specimen is then weighed, soaked in kerosene, and its volume measured in the kerosene-filled overflow volumeter. This method of testing has been developed by the Iowa State Highway Commission to the extent that close check results are obtained and many tests can be completed by two operators within 24 hr of their receipt in the laboratory. Moreover, the usual laborious work of drying and pulverizing the material prior to testing is entirely eliminated by this improved technique.

Application of Density Measurements.—Density measurements are utilized as follows:

(1) The ratio of shrinkage or swell which earth and rock masses undergo when transferred from "cut" to "fill" may be determined in advance by means of density values obtained from representative specimens of materials in place and also from the density value designated for the proposed road-bed;

(2) A means is furnished for computing pore space in bodies of earth in any state of compactness or wetness; and,

(3) Density measurements furnish a simple means of expressing the quality of earth compaction in numerical terms.

Standard density is utilized as follows: (*a*) As a distinctive and important property essential in the classification of earths proposed for structural use; (*b*) as a reproducible density, essential for specimens subjected to the hardness test; and (*c*) as a means for comparing the mechanical properties of thoroughly "welded" clays utilized in road-beds, with those utilized in the manufacture of clay products the mechanical properties of which have been measured. Experience has shown that the elastic limit and the yield point due to water content are to be preferred as standards of compaction instead of any standard based on density alone.

POROSITY

All matter is more or less porous. The large pores in deposits of gravel cannot escape detection. The pores in deposits of silt are not so obvious, but water readily finds its way into them. Even iron is known to be porous and, therefore, allows water under enormous pressure to be forced through it.

The invariable weakness of highly porous masses made up of minute cells which collect and retain large quantities of water has already been discussed. Therefore, attention will be directed to the discovery and measurements of pore space for the purpose of controlling it.

The measurement of pore space is sometimes attempted by the water-absorption method. When the pores are large and open, the water-absorption method may be saisfactory; but where pores are more or less closed and tortuous, the entrance of water is restricted. Hence, in the one case, the volume of water absorbed may be equivalent to that of the total pore space; but, in the other, only a small percentage of the total pore space may be filled.

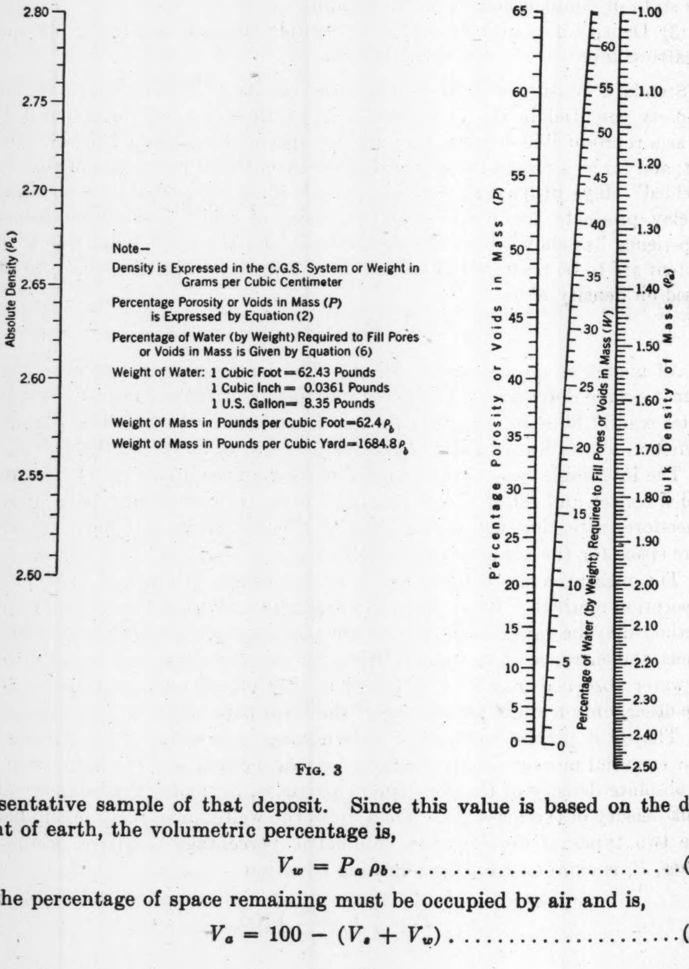
The most precise method of determining pore space is by computation. The essential measurements required for this method are: (*a*) Numerical value of absolute density of the constituent particles, ρ_a; and (*b*) numerical value of bulk density of the mass, ρ_b. Then, from the well-known relationship between the two types of density, the volumetric percentage of space occupied by pores, P, is expressed by the following equation:

$$P = \left(1 - \frac{\rho_b}{\rho_a}\right) 100 \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Obviously, Equation (2) may be applied either to cut, fill, or standard porosities by the substitution of actual numerical values for ρ_b and ρ_a. The volumetric percentage of solid matter, V_s, in a given road-bed is expressed by the following equation:

$$V_s = \frac{\rho_b}{\rho_a} 100 \qquad (3)$$

The percentage porosity of a given deposit having been determined by formula, then that part of the space actually occupied by water may be computed from the determination of percentage of moisture by weight made on a representative sample of that deposit. Since this value is based on the dry weight of earth, the volumetric percentage is,



Note—

Density is Expressed in the C.G.S. System or Weight in Grams per Cubic Centimeter

Percentage Porosity or Voids in Mass (*P*) is Expressed by Equation (2)

Percentage of Water (by Weight) Required to Fill Pores or Voids in Mass is Given by Equation (6)

Weight of Water: 1 Cubic Foot = 62.43 Pounds
1 Cubic Inch = 0.0361 Pounds
1 U.S. Gallon = 8.35 Pounds

Weight of Mass in Pounds per Cubic Foot = $62.4\rho_b$

Weight of Mass in Pounds per Cubic Yard = $1684.8\rho_b$

FIG. 3

$$V_w = P_a \rho_b \qquad (4)$$

and the percentage of space remaining must be occupied by air and is,

$$V_a = 100 - (V_s + V_w) \qquad (5)$$

The percentage of water by weight (P_w) required to fill the pores and voids completely in a mass of a given state of bulk density is equal to the percentage of voids in that mass divided by its bulk density; or,

$$P_w = \frac{P}{\rho_b} \qquad (6)$$

To facilitate the computation of pore space in earth masses and also to determine the quantity of water required to fill the pore space in these masses, the nomograph shown in Fig. 3 has been devised. This nomograph, which is based on Equations (2) and (6), can be used to demonstrate the inter-relationship of density, pore space, and water capacity of earth masses. This is a major concept of this paper.

Theoretical water capacity is the quantity of water necessary to fill the actual pore space in a mass of matter of known porosity. It may be expressed on a basis of either total dry weight or total dry volume. In this paper it is expressed as a percentage of dry weight.

TABLE 1.—CHARACTERISTICS OF CERTAIN FORMATIONS ENCOUNTERED IN ROAD BUILDING

Item No.	Material (1)	Density: Absolute (2)	Density: Bulk (3)	Porosity (4)	Percentage of water, by weight, required to fill the pores (5)	Characteristic bearing capacity (6)
	(a) MATERIAL IN ITS NATURAL STATE					
1	Average peat bed	1.50	0.20	86.7	433.5	Low
2			0.60	60.0	100.0	
3	Mica flake bed	2.88	0.40	86.1	215.2	
4	Diatomite bed	2.15	0.45	79.1	175.7	
5			0.96	55.4	57.7	
6	Volcanic ash bed	2.60	0.92	64.6	70.2	
	(b) MATERIAL IN "STANDARD" CONDITION OF COMPACTNESS					
7	Rock flour, or silt bed	2.65	1.20	54.7	45.6	Medium to low
8			1.50	43.4	28.9

16			2.22	16.3	7.3	
17			2.26	14.8	6.5	

* When moist.

Actual water capacity is the total quantity of water contained in a mass of earth that has ceased to absorb available water. Trial determinations for verifying the possibility of inducing further absorption may be made by means of shallow water-filled wells cut in the mass to be tested. Moisture determinations around wells, at short increments of distance from their centers, should be started after the rate of subsidence of water in the wells has been materially reduced or after a suitable interval of time of percolation from the wells. From these data and from the pore space previously determined, the percentage of pore saturation may be determined both for given distances from free water in the wells and also after given intervals of time of percolation.

Table 1 is shown for the purpose of familiarizing the reader with important inter-relationships of density, porosity, and water capacity of certain formations encountered in road building. (In the case of Items Nos. 14 to 17, Table 1, the determinations were made during the first "spring thaw." The actual mean percentage of water held was 2.4, the maximum was 2.7, and the minimum, 2.2.)

Brittleness, Elasticity, and Plasticity

The effects of stress are deformation and rupture. The mechanical properties of earths, like metals, may be classified, in a general way, in three groups: (*a*) Resistance to deformation and rupture; (*b*) capacity for deformation without rupture; and (*c*) work of deformation or rupture.

In Group (*a*), which may be designated by the general term, "hardness," are included the elastic limit, modulus of elasticity, compressive strength, transverse strength, shearing strength, endurance limit under repeated stresses, Brinell hardness, etc.

Group (*b*) may be covered by the term, "plasticity," and includes the relative compression without rupture in the compression test, the deflection at failure in the transverse test as well as the general properties denoted by the term, "malleability."

The work of deformation and rupture is the product of the resistance to deformation by the amount of deformation, and can be computed from the complete data of any test in which both load and deformation are observed continuously or at close intervals. It is represented by the area under the stress-strain curve.

The method used in the measurement of brittleness, elasticity, and plasticity is that usually followed to determine stress-strain relationships. Stress-strain tests are performed either on specimens in the laboratory or on the road-bed during construction. However, a sufficient number of both laboratory and field tests should be made for correlation after which field tests made by means of the roller should be adequate.

Tests on molded and dried specimens of known density can best be made in the laboratory. It is known that dried specimens possess an ultimate strength, show little elasticity, and fail suddenly under load. It is also known that very little moisture is required to develop elastic properties in earth in a well-compacted state, but exact information is lacking. Crusts of sand-clay roads carrying heavy traffic have been examined by the writer in which the moisture content was less than 4 per cent. The elastic properties of the crusts were not measured, but their condition under the traffic carried would lead one to infer considerable stiffness. Research on the quantity of water needed to change a brittle earth into an elastic one is needed.

Although the exact quantity of water necessary to develop the maximum elastic properties of compact bodies of earth is not known, it is known that an excess quantity not only weakens the elastic properties, but continues to do so in proportion to the increase in water content, until the yield point due to water content is reached. This is the point at which the material changes from the elastic to the plastic state as previously discussed.

Several investigators, including C. C. Williams,[14] M. Am. Soc. C. E., the late John H. Griffith,[15] M. Am. Soc. C. E., and others, have applied the principles of elasticity to the solution of problems in the mechanics of earth solids.

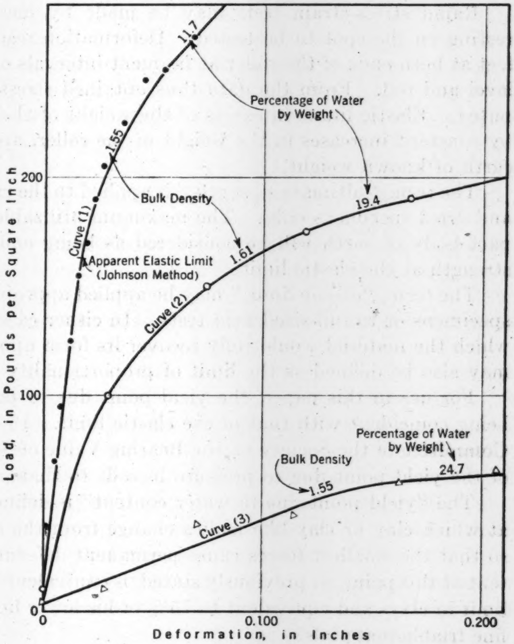

FIG. 4.—STRESS-STRAIN CURVES PLOTTED FROM TESTS ON A MASS OF EARTH COMPACTED TO INDICATED DENSITIES, AND WITH GIVEN MOISTURE CONTENTS

The application of the stress-strain method to the study of the elastic and plastic properties of bodies of a given earth is shown in Fig. 4. Earth utilized in these tests had been uniformly tamped in a cylindrical container of adequate diameter and depth for loading a 1-sq in. circular bearing-block. To prevent undue restraint against plastic flow, the distance between the bearing-block and the confining walls of the cylindrical container was spaced several inches. The loading was applied at a constant rate on all bodies tested.

Curve (1) in Fig. 4 was compacted to a density of 1.55, with a water content of 11.7 per cent. Its apparent elastic limit, as computed by the Johnson method,[16] is 164 lb per sq in. It will be noted from the several curves shown in the diagram that the stiffness of the bodies tested decreased with increasing water content. This is to be expected. Although Curve (2) is the densest body of earth tested, its water content causes it to show less stiffness than any, except the one having 24.7% of water. It will be noted that the stiffest and also the most plastic bodies tested had equal densities of 1.55; but the stiffest one contained only 11.7% and the most plastic one contained 24.7 per cent. With a water content of the latter amount, no elasticity whatever is indicated. This is to be expected since the water content in this case is 24.7% and that of the yield point due to water content is 20.1. A comparison of the water content represented by Curve (2) with that at the yield point due to water content, shows a difference of only 0.7 per cent. It will also be seen that this curve indicates little, if any, elastic properties. It does, however, indicate plastic flow under a limited load.

---

[14] "Foundations," by C. C. Williams, in "Civil Engineering Handbook," by L. C. Urquhart, M. Am. Soc. C. E. and others, pp. 632–659.

[15] "Physical Properties of Earths," by John H. Griffith, *Bulletin 101* (Iowa State College Eng. Experiment Station).

[16] "Johnson's Materials of Construction," by M. O. Withey and James Aston, Fifth Edition, 1935, pp. 9–10; also "Standard Specifications for Highway Materials and Methods of Sampling and Testing," adopted by the Am. Assoc. of State Highway Officials, 1935, pp. 291–303.

Rapid stress-strain tests may be made by means of a sheepsfoot roller resting on the spot to be tested. Deformation readings may be made on the feet at both ends of the roller at frequent intervals of time by means of a wye-level and rod. From the data thus obtained stress-strain data may be computed. Elastic limits in excess of the weight of the roller may be determined by constant increases in the weight of the roller, applied by means of bags of earth of known weight.

The term, "ultimate strength," is applied to the crushing strength of molded and dried specimens only. The maximum utilizable strength of a moist compact body of earth will be considered as being equivalent to its compressive strength at the elastic limit.

The term, "elastic limit," may be applied appropriately either to laboratory specimens or to full-sized field tests. In either case it is the unit stress below which the material would fully recover its form upon removal of the load. It may also be defined as the limit of proportionality between stress and strain.

For use in this paper, the yield point due to pressure will be regarded as being coincident with that of the elastic limit. In its 1921 report the Special Committee of the Society on the Bearing Value of Soils recognized the analogy of the yield point due to pressure in soils to that of the yield point of steel.[14]

The "yield point due to water content" is defined as the moisture content at which clay or clay-like bodies change from the elastic to the plastic state, so that the smallest forces cause permanent deformation. The moisture content at this point, as previously stated, is equivalent to Atterberg's lower plastic limit in clays and equivalent to 75% of his lower liquid limit in silts and other fine friable materials.

In regard to the inter-relationship of mechanical properties, both science and experience reveal that the magnitude of energy contained in a body is the measure of its capability to resist forces. Although one may not know the exact magnitude of a given form of energy possessed by a certain body, well-known laws aid in estimating the capacity of these bodies to resist certain types and magnitudes of forces. For example, the mechanical energy stored in hard or dense materials is known to be greater than that of soft or less dense ones. As a further example it may be stated that the hardness of steel, as determined by the Brinell method, has a direct relation to the tensile strength, and is equal to the product of a coefficient, C, into the hardness number.[17]

---

[17] Mechanical Engineers' Handbook, by William Kent, Ninth Edition, Rev., 1916, p. 365.

Moreover, if a given material shows considerable tensile strength, one may reasonably expect it to be able to offer considerable resistance to shear, compression, etc.

Other conditions being equal, dense materials, including clays, clay products, concrete, stone, wood, and metals are stronger and harder than their more porous respective equivalents. With respect to the strength of earths, Williams states:[14] "The supporting capacity of sands, gravels, clays and other earths, within the range of each soil type, varies approximately with the weight per cubic foot." He states furthermore that a committee of the Society "from a study of the influence of colloidal content of earths upon their behavior under pressure, found the strength of loam and clay specimens increased with the percentage of colloids contained."

Gumbo clays, noted for their high liquid limit (water-fusing point), possess the highest tensile strength of any known clay. In contrast, kaolins have low liquid limits and also are among the weakest of clays. Moreover, the strongest metals generally have a high fusing point, a good example of which is tungsten wire, the strongest metal known, which has a fusing point of 6 152° F. In contrast to the strength of tungsten wire, lead is one of the weakest of metals, and it also has one of the lowest fusing points of metals.

The relationship between density and elasticity of earth masses is quite marked. Loose masses (low density) under stress manifest no elastic properties, but solidified masses (high density) show elastic properties as do other solids under stress. Increasing the density of a given body is equivalent to increasing its elasticity.

Considerable experimental data on the inter-relationship of the several manifested forms of energy in given bodies have been published by Griffith.[18] He shows certain relationships between the strength of bricks and rocks and their absorption and hardness. In each of the *Bulletins* mentioned he discusses the structural organization of matter and shows the similarity of laws governing different forms of energy, including elasticity, plasticity, hardness, density, etc. In support of his experiments and hypotheses, he cites the findings of others among whom are included A. E. H. Love[19] and A. Nadai.[20]

Detailed studies based upon experimental evidence of the relationship between stress and strain in masses of earth of certain density and moisture content should reveal a wealth of information to the highway engineer. In like manner, the effect of admixtures of sand and clay on the development of structural properties of road-beds could also be determined.

DESIGN OF ROAD-BEDS

Obviously, the design of road-beds should be based on the essential structural requirements outlined and discussed in detail in this paper. Information obtained from large transportation companies, tire manufacturers, and producers of heavy equipment show that the pressures in balloon tires now rarely exceed 75 lb per sq in., with a tendency toward much lower pressures. Inflation pressures of tires do not now exceed 100 lb per sq in. Therefore, it seems safe to assume a maximum wheel pressure on the road to be 100 lb per sq in. Due to the limited use of solid rubber tires, these tires are not to be considered.

[20] "The Phenomena of Slip in Plastic Materials," by A. Nadai, *Proceedings*, A.S.T.M. (1931), Pt. 2, pp. 11-26; also "Plasticity," by A. Nadai, McGraw-Hill Book Co., New York, 1931.

Factor of Safety Against Pressure.—To avoid the possibility of over-stressing the road-bed, the application of a factor of safety seems essential. Following the usual custom, it would seem that the minimum factor of safety recommended should be not less than 2. Based upon the maximum tire pressure of 100 lb per sq in. and a factor of safety of 2, the road-bed should be designed for pressures not less than 200 lb per sq in.

Elastic Limit Required.—To meet the load requirement, obviously the material of which the road-bed is to be made must be capable of being formed into a solid having an elastic limit not less than that required for the given load and safety factor against pressure, or not less than 200 lb per sq in.

Stiffness Required.—Obviously, the stiffness of a road-bed should be developed adequately to resist the load for which it is designed; but before any numerical value of stiffness can be set up as a standard, considerable field and laboratory data must be obtained. Moreover, until a satisfactory standard of stiffness can be established the designing engineer should make every effort possible to develop much needed data on this feature of road-bed design.

Development of Hardness, Elasticity, and Stiffness.—The properties of hardness, elasticity, and stiffness may be developed in wet coherent material in either of two ways. A reduction of water content will develop these properties to some extent, provided the pore space is not too voluminous; but since the capacity for holding water is predicated on the available pore space, these properties of strength may best be developed by increasing the density of the road-bed under controlled moisture conditions.

If the road-bed is too wet to be compacted, its density may be increased by the well-known method of adding dry sand, gravel, or other hard rock fragments and pounding the added material into the wet spongy mass. By this process, densities of 2.20 or more may be developed in a layer of desired thickness. Obviously, the greater the thickness and density of the layer thus built, the greater will be its resistance to mechanical forces. Sand, fine gravel, or fine crushed stone is to be preferred since fine pores offer greater resistance to the passage of wet clay than coarse ones. Aggregates graded in sizes from that of silt to that of gravel are essential in the rapid choking of the pores. Moreover, the aggregate must be cemented into a solid mass by means of clay or other adhesives.

Where a thin layer is sufficient, the work may be accomplished by the use of a tamping roller applied to thin layers of aggregate. Where rigid and dense layers of considerable thickness are to be placed across swamps, the use of a heavy rammer of the pile-driver type is essential for constructing the lower part of the densely constructed stratum.

Factor of Safety Against Water Absorption.—This factor of safety must be determined by actual test prior to the work of designing. From actual compaction tests, determine a density which gives an actual water capacity, less than the quantity of water required to produce the yield point due to contained water. Then, from these data,

$$S_W = \frac{s_{yw}}{P_a} \qquad (7)$$

in which S_W = the factor of safety against water absorption; s_{yw} = the yield point stress due to water content; and P_a = the actual water capacity of pores, expressed in terms of percentage by weight. The true criterion for determining what density is essential for a road-bed is the relationship between actual water capacity and the yield point due to contained water. This relationship seems to be expressed best in the form of the "factor of safety against water absorption." It is this relationship which controls the water softening of the road-bed. That compacted bodies of earth offer a greater resistance to water softening than bodies of loose earth was probably first discovered by prehistoric Man as he walked along a path loosened here and there by some burrowing animal just before a rain; but since the writer is not aware of an existing method for determining the critical point of softening and then guarding against its occurrence, he has been forced to apply the method now termed, "factor of safety against water absorption."

Many bituminous mat-road surfaces which had failed due to the apparent weakness of the road-bed have been examined. Of these failures, no case is recalled in which the bulk density of the road-bed was in excess of 1.50. Based on this value of bulk density and on an absolute density of 2.65, the pore space is found to be 43.4% and the theoretical water capacity, therefore, is 28.9 per cent. A pore space of this magnitude will probably have an actual water capacity almost as great as its theoretical capacity. Since the yield point due to water absorption in many clays is less than 28.9%, the reason for the occurrence of many failures in road-beds having a density less than 1.50 becomes evident.

As a basis for further study and research, the writer offers the following limiting values for use in designing road-beds:

(*a*) Do not allow the pore space in the road-bed at depths greater than 2 ft below subgrade, to exceed 40% of the volume;

(*b*) Reduce the pore space in the upper 2 ft of the road-bed so that its theoretical water capacity shall be not greater than 70% of the lower plastic limit of the earth used in forming the road-bed.

Materials Balance Factor.—As previously stated, this factor is based upon the ratio of density of mass in a fill to that in a cut. The results to be expected from the use of this factor depend entirely upon the precision of the original weighted density values obtained and also upon the precision with which the compacting specifications are executed.

Road-Bed Protection.—Experience teaches that thoroughly compacted deposits of earth do not change in volume unless acted upon by outside forces.

Bench-marks set below the frost line in wet earth or even on tree roots have been found to remain stable unless they come within range of landslides or destructive earthquakes. Even deposits of clay subjected to enormous pressures through long ages do not bulge when the pressures are removed by the excavation of the overlying deposits. Moreover, there is no such thing as a "natural density" for any given material, regardless of its environment. For example, a given type of clay should be expected to have densities proportional to its compacting environment—that is, they should be low in arable fields, higher in old pastures, and still higher in well-trodden paths, or in barnyards.

The agency most destructive to compacted road-beds is weather. It matters not how well a road-bed may be compacted, if it is left exposed to weather, the exposed part should be expected to become less dense. Therefore, the greater the number and magnitude of weather changes, the greater the change to be expected in the original density.

To prevent the weather from producing marked changes in road-beds, they must be shielded against its influence. Ground-water must be intercepted and surface water must be diverted from the entire road-bed, including the shoulders. A pavement or bituminous surface alone is not sufficient protection against the weather. Pavement cracks generally develop and joints are seldom water-tight. For this reason provision should be made to prevent excessive moisture changes near the subgrade and in the shoulders. Some form of effective stabilization seems to be the only method of preventing road-bed softening and plastic flow in the region of the subgrade which leads to pavement sag, rupture, and faulting.

CONSTRUCTION METHODS AND EQUIPMENT

Organized Personnel.—Before any grading work is to be started, the resident engineer should organize the inspection service and make certain that everything is ready for construction operations. All data that have been collected must be compiled on the plans and shown as part of the road-bed design. The moisture conditions of the material to be excavated must be ascertained immediately before construction work is to be started.

Systematic Inspection.—The system of inspection must be planned so that an inspector is constantly on duty while road-bed construction is in progress. The minimum number of tests allowable should be specified. Results of tests should be recorded by station and elevation.

Testing Equipment.—Field-testing equipment should be portable in type and located conveniently near the center of construction activity.

Control of Materials and Methods of Construction.—The essential qualifications for the proper execution of this work are: (*a*) Thorough knowledge of the inherent structural properties of the road-bed materials to be found; (*b*) methods by which these materials may best be utilized in the construction of the road-bed; and (*c*) essential diplomacy and firmness of purpose in dealing with the contractor.

The inspectors should be competent to advise with the contractor in all details of the work. They should aid in planning the work so that construction operations may be made to fit the weather with the least delay, but under no circumstance should they allow weather conditions to lower the quality of the work. Basin-like areas must not be permitted—either in excavation or in embankment—at any time. These areas may collect water and hinder the work. All embankments should be completely compacted and finished with a smooth surface before closing the work at any time.

CONCLUSIONS

Five pertinent conclusions are supported by the foregoing text:

(1) The structural properties of earth masses are enhanced by increasing their density;

(2) The resistance offered by earth masses to the penetration of water increases with increasing density;

(3) The porosity of earth masses can generally be decreased to a certain value by means of a roller; but the porosity of granular masses such as gravel, sand, and silt, can be reduced best by the use of suitable admixtures followed by heavy rolling;

(4) A satisfactory standard of compaction is that based on a suitable factor of safety against water absorption; and

(5) Surface protection against the ravages of weather on clay-like matter is essential, regardless of the degree of compaction.

ACKNOWLEDGMENT

The principles set forth in this paper are from various sources. Most of them are well known, especially in other fields of work, and all are believed to be in accord with fact. Working hypotheses were first written and then tested by a series of observations and researches, most of which were done on the field, covering hundreds of miles of roads of the several types of materials already described. Conclusions were not formed until these hypotheses had been either abandoned or verified by competent evidence.

The work was done as a part of the writer's official duty as a Supervising Engineer in the United States Bureau of Public Roads on Federal Aid work. Clifford Shoemaker, M. Am. Soc. C. E., District Engineer, had long recognized the need for more stable road-beds and, in 1931, directed the writer to give special attention to this feature of the work. For this opportunity and for many helpful criticisms the writer acknowledges his grateful appreciation. Acknowledgment is also made to the Engineers of the several State Highway Departments in the District for their splendid co-operation in the collection of data used in the development of this paper.

DISCUSSION

A. F. Greaves-Walker,[21] Esq. (by letter).—An excellent argument for the necessity of a better knowledge of ceramic materials and ceramic fundamentals on the part of highway engineers is presented in the paper by Mr. Mullis, which describes the properties of the ceramic materials used in highway construction very well. A study of these properties should be helpful to all highway engineers, and particularly to those who are confronted with the problem of constructing long-lived secondary highways.

There is no question about the structural properties of earth masses being enhanced and made more highly resistant to water penetration by increasing their density. Considerable research work has been done by ceramic engineers in an effort to produce maximum density in both plastic and non-plastic bodies. In plastic bodies (clay), it has been found that the addition of acids or bases, depending on the pH-value of the clay, will increase both the plasticity of the mass and the dry density. Common or waste acids, or such bases as lime, calcium chloride, salt cake, soda ash, etc., may be used, but care must be taken to add the correct quantities. This depends on the pH-value of the material. Under any circumstances only small quantities are required to give desired results.

Much research has also been done on particle packing, and from the results it is possible to calculate beforehand the percentages of the coarse, medium, and fine fractions necessary to obtain the maximum density with any particular material or materials. Clays vary widely in their mineralogical composition and especially in their content of "clay substance," the colloidal hydrous aluminum silicate which gives to clay its peculiar properties. The content of "clay substances" controls the bonding power. Many clays which to the "feel" are extremely plastic have low bonding power, due to a low content of "clay substance." When used as binders such clays produce "open" or porous bodies when dry, and thus readily absorb water.

Pressure is very important in producing dense bodies when either clay-bonded or non-plastic masses are considered. With increased pressure the water of plasticity can be reduced increasingly which, in turn, reduces shrinkage where clay bonds are used.

The effect of pressure on density varies considerably with the materials. Non-plastics like crushed stone which have hackly fractures, offer great resistance to movement under pressure, whereas smooth materials like gravel offer much less. Consequently, under equal pressure, the gravel will form the denser mass provided both are composed of fractions of the same size.

Mr. Mullis' investigations are unquestionably along lines that will result in greatly improved road-beds and fills. In the manufacture of a good ceramic product and the making of a good road-bed there is much common ground.

---

[21] Pres., The Inst. of Ceramic Engrs.; Prof., Ceramic Eng., Univ. of North Carolina, Raleigh, N. C.

H. Z. Schofield,[22] Esq. (by letter).—It is of much interest to note that the conclusions (notably Conclusions (1) and (2)) of this paper are verified by results of researches on the effect of de-airing the earth materials used in the stiff-mud manufacture of structural ceramic products.

By stiff-mud extrusion from a laboratory brick machine, Messrs. J. O. Everhart, C. R. Austin, and W. C. Rueckel[23] prepared specimens of three shales, a glacial surface clay, an alluvial surface clay, three coal-formation clays, a stoneware body, and a table-ware body. Duplicate specimens were then prepared in which the materials, immediately before extrusion from the brick machine, were de-aired by direct evacuation of air from the chamber of the brick machine. The effect of de-airing (and the consequent reduction in porosity and increase in density) on the physical properties was then determined. De-airing increased plastic strength both in tension and compression; it increased the dry transverse strength and modulus of elasticity; and, in all but one case, it caused a marked increase in the water-slaking time of the dry specimens.

W. H. Campen,[24] Assoc. M. Am. Soc. C. E. (by letter).—Much care has gone into the preparation of this paper. Mr. Mullis should be especially commended: (*a*) For his analysis of the steps involved in densifying water-soil mixtures; (*b*) for the classification for road construction of a number of typical soil deposits; (*c*) for clearly showing the effect of water content on the structural properties of soils; and (*d*) for the application of the information in the design of road-beds.

He assumes that a maximum pressure of 100 lb per sq in. is applied to surfaces on highways and then suggests that the entire upper 2 ft of the road-bed be constructed to support this load. There is no doubt in the writer's mind that, if all the soil or soil-mixture courses within this thickness are compacted so as to restrict their water capacity to 70% of their plastic limit, the resistance required will be developed. However the pore space called for is lower, and the thickness is higher, than is necessary for satisfactory road-beds. Some tests made in connection with the construction of the runways of the Omaha (Nebr.) Airport and other roadways will support the writer's contentions.

Assume that a road is required to carry, safely, and at all times of the year, a vehicle having 10 000-lb wheel loads and 100 lb per sq in. of air pressure in its tires. Assume, furthermore, that a soil is available which will pass a No. 40 sieve (with a plastic limit of 20); and a soil-gravel mixture containing material 27% smaller than a No. 40 sieve (plastic limit, 20). The relation between the load-bearing value and the water content, in dry weight per cubic foot, or pore space, is shown for these materials in Table 2. Column (3) is obtained by dividing the percentage of water used by the water content of the sample at plastic limit, and multiplying by 100. The plastic limit is determined on the part of the mixture that passes a No. 40 sieve.

[23] *Bulletin No. 74*, Ohio State Univ. Eng. Experiment Station, November, 1932.

[24] Pres. and Mgr., Omaha Testing Laboratories, Omaha, Nebr.

The mixture is compacted in a mould 8 in. in diameter and 4 in. deep. Without removing the base of the mould a round bearing plate, 2 in. in diameter, is placed in the center and loaded until a $\frac{1}{8}$-in. penetration is produced. The load, supported for 5 min at this penetration, is converted to pounds per square inch (see Column (7), Table 2). Readings can be taken at other penetrations but $\frac{1}{8}$-in. is taken as representative of surface failure.

TABLE 2.—RELATION BETWEEN LOAD-BEARING VALUE AND WATER CONTENT

WATER CONTENT EXPRESSED AS A:			AGGREGATE		Percentage of air voids	Load-bearing value, in pounds per square inch
Percentage of the Dry Weight		Percentage of the plastic limit	Weight per cubic foot, dry	Percentage by volume		
By weight	By volume					
(1)	(2)	(3)	(4)	(5)	(6)	(7)
(*a*) SOIL (SPECIFIC GRAVITY, 2.62)						
25.5	39.3	127	96.2	59.0	1.7	13
24.5	38.8	122	98.6	60.5	0.7	18
22.7	37.2	113	102.5	62.9	0.0	30
20.3	35.7	101	105.6	64.8	0.0	41
19.6	33.8	98	107.4	65.9	0.3	55
18.3	32.3	91	110.0	67.5	0.2	100
17.0	30.1	85	111.0	68.1	1.8	200
16.5	28.9	82	109.1	67.0	4.1	....
(*b*) SAND-GRAVEL BINDER MIXTURE (SPECIFIC GRAVITY, 2.61)						
10.4	21.3	180	127.0	77.8	0.9	13
8.1	17.2	137	132.3	81.2	1.6	42
7.4	16.1	124	134.7	82.7	1.2	200
6.4	13.7	106	133.5	81.9	4.5	320

As shown by Mr. Mullis, the load-bearing value (he calls it the resistance to pressure) increases as the density increases, or as the pore space decreases, it being understood that the pore space is nearly filled with water. It is to be noted also that at maximum density the load-bearing value is 200 lb per sq in. for both materials, and that the water content is 85% of the plastic limit in the case of the soil (Column (3), Table 2), and 124% in the case of the soil-gravel mixture (allowance is made for 1% absorption in the coarse aggregate). Since a resistance of 200 lb per sq in. satisfies Mr. Mullis' requirements, it would be wasteful to compact with less water and to a higher density. It might be added that the results obtained with the two materials given are representative of mixtures in general within the writer's experience. These tests have been made on soils having plastic limits of from 15 to 33, and on soil-coarse aggregate mixtures having plastic limits of 10 to 30 and maximum sizes as great as 2 in.

As to the thicknesses required: Since it is good common practice to use a coarse aggregate mixture, covered with a bituminous mat, on the upper part of the road-bed, assume that the upper part of the road will be composed of 2 in. of mat and 6 in. of a soil-gravel mixture. The mat will reduce the 100-lb load by distribution so that only 57 lb will be delivered to the base. The base (Table 2(*b*)), packed to maximum laboratory density, can safely handle this load, and, in turn, will deliver a load of about 17.5 lb per sq in. to the sub-grade. For adequate protection the sub-grade should be constructed to support twice this load, or 35 lb. The soil shown in Table 2(*a*) will do this job well if compacted with a water content equivalent to 101% of its plastic limit, or to 95% of laboratory density.

The next question is: How thick shall the compacted sub-grade be made? The full 16 in. demanded by Mr. Mullis would deliver a load of about 7 lb to the 24-in. level (it is assumed that the compacted soils have a load distribution ability equal to 50% of the coarse aggregate mixture). There are many locations where this type of construction is needed because of the water content of the natural sub-grade. There are other locations (and they are much greater in number) where the soils have pore spaces of about 50%, but where water can be prevented from reaching them. At these locations the water content is such that high load support prevails. In these cases, then, advantage should be taken of the high sub-grade support and the construction should be limited to compacting the upper 6 in. to 90% of laboratory density. As a matter of fact, many heavily traveled highways are built on this principle and would fail if enough water could reach the sub-grade to fill the pore space.

Mr. Mullis' requirement of not more than 40% of pore space in materials below the 2-ft level is reasonable except when applied to certain types of clay; but, as has been stated herein, this should only be considered where water might be accessible. In connection with this condition, it must be borne in mind that the load-bearing value at any given water content varies with the plasticity index. For instance, a clay that has a plasticity index of 60 has a load-bearing value of 100 lb per sq in. at a 26% water content, whereas a soil having a plasticity index of 30 has only a 25 lb per sq in. load-bearing value at the same water content.

The construction and successful performance of runways at the Omaha Airport will serve as an example of the writer's contentions. A typical cross-section shows 1-in. sheet asphalt, 2-in. asphaltic concrete binder, 6-in. soil-gravel mixture, and 6-in. compacted soil. The base was compacted to a maximum density and the sub-base (the upper 6 in. of the sub-grade) was compacted to at least 95% of maximum density. The undisturbed sub-grade is saturated with water and has a maximum pore space of 50 per cent. A modern airplane having a wheel load of 13 500 lb and 51 lb of pressure in its tires has operated for two years on parts of the runways without any signs of failure.

BERNARD E. GRAY,[25] ESQ. (by letter).—It is indeed encouraging to find attention being given in larger measure to the problems of earth foundations, because through application of even the broader principles governing soil densities, great saving in construction costs, particularly of highways, may be obtained. Mr. Mullis has outlined these principles in a concise and logical manner.

It is unfortunate indeed that so many engineers have only a slight knowledge concerning soil behavior and are little concerned about it. This attitude arises from a fundamental misconception in regard to the place of soil in the construction "picture." To many, "dirt is dirt," and their designs are usually made massive to take care of the worst anticipated conditions, with no thought or provision for possible modification of the soil itself. To check the truth of this statement, it is only necessary to watch some heavy grading job, and to note the blithe manner in which the weathered and more stable soil is placed at the bottom of a fill, and the raw, unstable soil on the top. The writer assumes no virtue in this regard, having built many, many miles of highway over past years in just the same wrong manner, but, in the light of present knowledge, such practice should be modified, and the valuable stable soils should be saved and utilized in the sub-grade where they belong. When engineers begin to think of relative values in soils as they do for the various manufactured structural materials, then they will be truly on the way to making some genuine savings in foundation designs.

---

[25] Chf. Engr., The Asphalt Inst., New York, N. Y.

Shear necessity is the most compelling motive to action, and about 1918 the writer, in making a study of old survey notebooks covering highway locations in Virginia and West Virginia, was impressed with the comments therein respecting the character of the ground traversed. The party chief had carefully noted his proposed location with especial reference to soils and their behavior under temperature and moisture changes. Some of these soils had remarkable stability, as evidenced by their solid condition under wagon traffic, so much so that when the writer later built modern type roads, largely on these old locations, he experimented by placing variable thicknesses of macadam over the most stable soils. In one particularly good section, only 3 in. of limestone macadam was built using the compacted soil as a base, except for a thin layer of screenings and dust placed over the soil as a leveling course. This section is still (1938) under traffic and its behavior has been better than some of the 8-in. and 10-in. adjacent sections having sub-grades of less bearing power.

On some of the secondary roads, bituminous surface treatments were placed directly on these soils and served traffic adequately for a number of years before additional thickness was required to distribute the increasing wheel loads better. Taking advantage of these favorable conditions it was possible to improve the system as a whole many years sooner than would have been the case had conventional designs only been used.

There is little to criticize in Mr. Mullis' paper, but perhaps some emphasis on certain paragraphs may be helpful, as follows: Under the heading, "Loose, Amorphous, Plate-Like, Fibrous, and Cellular Matter," he states: "Loose material, regardless of other attendant structural properties, should have no place in a road-bed." Nothing could be more true, and yet it is continually disregarded. Many bases have failed, not because of poor quality, but because they were not consolidated, and the surface placed thereon became distorted later as further compaction occurred under traffic. It is common practice to write specifications as to thickness of such courses, and quite uncommon to have any standard as to density of the completed work. Without such density control, thickness is a meaningless measurement. Time and again, thicknesses have been increased, when all that was required was to obtain uniform density of the thinner layer. This conclusion is borne out in the statement by Mr. Mullis in the text following Equation (7):

"Many bituminous mat-road surfaces which had failed due to the apparent weakness of the road-bed have been examined. Of these failures no case is recalled in which the bulk density of the road-bed was in excess of 1.50. * * * the theoretical water capacity, therefore, is of 28.9 per cent."

Regardless of pavement type, it should be recognized that stabilized road-beds are required for long life and low cost of repairs.

Under the heading, "Brittleness, Elasticity, and Plasticity," it is stated that: "Loose masses (low density) under stress manifest no elastic properties, but solidified masses (high density) show elastic properties as do other solids under stress."

The rational design of the so-called "flexible type" pavements is predicated upon this axiom. It applies both to the road-bed and the pavement. When road-beds (sub-grades) are designed for a given minimum density under the most adverse conditions, it is then a simple matter to calculate the depth of pavement required to distribute wheel loads so that its bearing capacity is not exceeded. In respect to wheel loads, the comment under "Design of Road-Beds" should be noted. Balloon tires have modified pavement design. Present wheel loads are so distributed over a large contact area that there is little, if any, more destructive action under the heaviest vehicle than was formerly experienced under a two-horse wagon. As Mr. Mullis states, present tire pressures are rarely in excess of 75 lb with the trend toward less pressures. Thus, a design load of 200 lb per sq in. gives an ample margin of safety.

Under the heading, "Design of Road-Beds: Road-Bed Protection," it is stated that:

> "The agency most destructive to compacted road-beds is weather. * * * A pavement or bituminous surface alone is not sufficient protection against the weather. Pavement cracks generally develop and joints are seldom water-tight. For this reason provision should be made to prevent excessive moisture changes near the sub-grade and in the shoulders."

This is a most pertinent comment, and should have much influence on design. The increased use of bituminized shoulders and sub-grades is recognition of the need for preventing water from softening sub-grade or shoulder support. A striking example of the merit of such protection is to be found in Connecticut, where during the flood of September, 1938, practically no damage occurred to pavements where such shoulder protection was used.

Although the inherent values of designed sub-grades are not yet widely appreciated, a few engineers have begun to build roads by such means. Some question has arisen in respect to the rational design of flexible pavements making use of variable sub-grade support. Valuable contributions on this subject have been made by W. S. Housel,[26] Assoc. M. Am. Soc. C. E., W. S. Downs,[27] A. T. Goldbeck,[28] and G. E. Hawthorn,[29] Members, Am. Soc. C. E., and many others. Although there may be some difference of opinion as to the manner of stress distribution in soils, the conventional distribution for an elastic solid is certainly conservative for designed bituminous mixtures of known stability. Accordingly, the writer suggests a formula to control design thickness that gives results which, in the light of road behavior, are more than adequate for modern traffic.

[28] "Researches on the Structural Design of Highways by the United States Bureau of Public Roads," by A. T. Goldbeck, *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 264.

[29] "A Method of Designing Non-Rigid Highway Surfaces," by G. E. Hawthorn, *Bulletin 83*, Univ. of Washington, August, 1935.

In the usual equation, the pavement thickness is calculated by assuming that the load is applied at a point, whereas actually it is applied over a considerable area depending upon the character of the vehicle and its tire equipment. Although this area varies with different loadings and different pressures (in pneumatic tires), Table 3 shows the average conditions in round numbers.

TABLE 3.—AREA OF TIRES IN CONTACT WITH ROAD

Description	UNIT WHEEL LOAD, IN THOUSANDS OF POUNDS:				
	2	4	6	8	10
Area of tire or tires in contact with road, in square inches.....	25	57	75	95	112
Radius of equivalent circle, in inches..................	2.8	4.2	4.9	5.5	6.0

L. W. Teller and J. E. Buchanan,[30] Assoc. Members, Am. Soc. C. E., indicate that maximum load intensities occur in two transversely symmetrical zones rather than at the geometric centers of the areas, and the differences in load per square inch are not as great as was formerly supposed.

It is apparent, therefore, that in place of a cone of distribution, there is actually the frustum of cone, and that the true radius of the area of load distribution over the base or sub-grade is equal to the thickness of the pavement plus the radius of tire-area contact.

In Fig. 5, let W = wheel load, in pounds; s = safe bearing value of the subgrade, in pounds per square inch; t = required thickness of pavement, in inches; r = radius of cone; and e = the dimension shown.

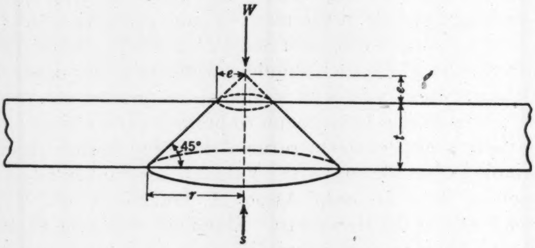

FIG. 5

Then,

$$W = \pi r^2 s \qquad (8)$$

---

[30] "Experimental Determinations of the Variations in Pressure Intensity Over the Contact Area of Tires," Highway Research Board, December, 1937.

but, $r = t + e$; and $W = \pi\,(t + e)^2\,s$; that is,

$$t = 0.564\sqrt{\frac{W}{s}} - e \text{ . . . . }(9)$$

The bearing capacity is composed of two separate factors of strength, one which is dependent upon the perimeter of the area, called perimeter shear, the other dependent upon the area itself, termed the strength of the pressure bulb. This latter factor often has been the only one given consideration in determining the thickness of flexible pavements, and yet in bearing areas of small size, the factor of perimeter shear, in giving support value to the sub-grade, may be the larger of the two. Professor Housel,[26] who has made a number of studies in this regard, gives the following equation for these relationships:

$$W = A\,S = m\,P_A + n\,A \text{ . . . . }(10)$$

in which W = total load carried on a given area, in pounds; A = area, in square feet; P_A = perimeter of area, in feet; m = perimeter shear, in pounds per linear foot; n = developed pressure, in pounds per square foot; and, S = bearing capacity, in pounds per square foot $= m\frac{P_A}{A} + n$.

In 1932, Roland Vokac,[31] Assoc. M. Am. Soc. C. E., then with the Michigan State Highway Laboratory, reported some very informative studies in connection with the design of low-cost bituminous mixtures. Making use of Equation (10) (expressed in inches instead of feet to conform to the size of suitable laboratory samples) he found that the values of m and n could be determined for any mixture through the use of a simple laboratory machine. Numerous mixtures of varying behavior under traffic were tested and the laboratory results consistently confirmed the road behavior, not only relatively, but in accurate fundamental terms of bearing capacity. Also, contrary to the general assumption that the highest concentration of pressure always occurs under the center of the loaded area, it was found that up to certain loads there is actually a negative value for n because the perimeter shear value, m, is so high that all the load is carried at the edge of the bearing area. As the load further increases this shear value builds up first, followed later by the increase of pressure resistance until both become constant, at which point the ultimate strength of the material is reached.

Professor Housel also shows that,[26] "The importance of the time element in interpreting the results of test on all varieties of soils cannot be over-emphasized." By this is meant the difference in the effect of load distribution between a load suddenly applied and then immediately removed, and one applied gradually over a longer period of time. An interesting example of this difference is familiar to all in the incident of school days in sliding across thin ice without difficulty where it would have been impossible to have walked across without breaking through. Still another factor contributing to the supporting power of a sub-grade is the effect of surcharge due to the weight of a superimposed layer of well bonded material. This is particularly marked in sub-grades which depend principally upon internal friction for stability and in which there is little cohesion, as in the case of loose sand.

---

[31] "Studies in the Proportioning of Low Cost Bituminous Mixtures of Dense Graded Aggregate Type," Tenth Annual Asphalt Paving Conference, 1932.

Although this discussion could be prolonged indefinitely without exhausting its potential values, it is hoped that some additional attention may have been focused upon the paper of Mr. Mullis. It is believed that the following conclusions can be derived from reading it:

(1) Although various types of road surfaces have been used over a long period of time, only in the past few years has there been any effort to appraise conditions under which they should be selected and utilized in relation to traffic needs.

(2) The most important part of the road structure (the natural soil foundation) has been almost completely ignored in making an engineering analysis. Even now only a few States follow any definite procedure in this regard.

(3) There are two methods of designing a road surface: (*a*) To make it so thick that it stands in spite of a bad foundation; and (*b*) to place a wearing course exactly thick enough to supplement the sub-grade support. The first method often entails unnecessary expense.

(4) There is always a way to utilize local materials for road construction; it only requires intelligent engineering study to develop the requisite technique. This is particularly true in respect to sub-grade stabilization.

(5) The load supporting capacity of a sub-grade depends upon two characteristics: Internal friction and cohesion between the particles making up the soil. These vary according to the moisture content (especially the latter), and beyond a critical point result in reduced capacity to carry load.

(6) Control of moisture content, then, is of the greatest importance and yet engineering attention to this matter is often more a matter of talk than of action.

(7) Having controlled moisture through appropriate methods according to job conditions, it is then required to determine the thickness of surfacing for traffic. This involves two studies, one as to the minimum support to be derived from the sub-grade, either natural or as modified, and the other as to the capability of the selected surface, to transmit load without distortion. Soil classification has proceeded to the point where a relatively few general groups cover all locations, so that all that is required is to apply methods for measurement already established in other fields. There are several laboratory machines for determining the stability of wearing course mixtures. There only needs to be a greater use made of these methods and facilities.

(8) To utilize inherent soil values to best advantage, work should be done in a uniform manner. By proper attention to grading operations the finished sub-grade can be made of uniform load-supporting character, with resulting uniformity in wearing course. It is less expensive to prepare a high support sub-grade with a relatively thin surface course to meet a given traffic load, than to build a thick surface on a "hit or miss" sub-grade. What seem to be low prices for unclassified excavation in road-grading operations are often actually very costly because good soils are frequently wasted.

(9) According to well-known laws it is possible to use a formula for the determination of the necessary thickness of wearing course to meet any condition. That this formula is not the same as the one used in designing rigid pavements is simply a recognition of the fact that there are basic differences between elastic and plastic substances.

W. J. TURNBULL,[32] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper, the author has presented a clear picture of the functions of a soil in a road-bed. He has reviewed the various states of matter and the way in which each one influences the action of a soil in the road-bed, when placed at varying degrees of compaction. The definitions of the various characteristics of a soil, as well as the various soil types, are believed to be especially good.

The gist of the paper, as interpreted by the writer, is to the effect that increasing the soil density: (1) Enhances the structural properties of the soil; (2) increases its resistance to water penetration, thus acting to decrease weathering ravages; and, generally, (3) improves the desirability of the soil in all respects as the principal component in a road-bed. In general, this is true. However, some soils are known to have more detrimental swelling properties at the higher densities, and, consequently, this feature should not be neglected in the study of a soil to be used in a road-bed.

Mr. Mullis introduces the term "yield point due to water content" as marking the end of the elastic state and the beginning of the plastic state. He also states that it is approximately equal to Atterberg's lower plastic limit in clays, and to 75% of Atterberg's liquid limit in silts and fine, friable materials. Further, the inference is made that the plastic state is undesirable. The writer feels that the early stages of the plastic state are not undesirable provided the strain produced in the road-bed on the application of the maximum wheel load is not beyond an amount which is harmful to the surface-protection mat. This is analogous to the fact that a structure may withstand successfully 2 in. of settlement, whereas 4 in. would be very harmful. The early stages of the plastic state may even be more desirable than the early stages of the elastic state, due to the fact that the latter borders near brittleness; whereas the strain in the former state produced by the maximum wheel load is not detrimental to the wearing surface. As stated by the author, a brittle (dry) road-bed is undesirable unless the soil possesses high tensile strength, which very seldom if ever occurs. Furthermore, the elasticity of a soil increases with increasing density, other factors remaining equal. The preceding statements have been made on the assumption that a soil placed at a given density passes through the brittle state into the elastic state and into the plastic state with increasing moisture content.

In the design of the road-bed, the author indicates the "factor of safety against water absorption" as the ratio of the "yield point due to water content" (lower plastic limit) to the actual water capacity of the soil. He further indicates that the top 2 ft of a road-bed should have a factor of safety of 1.43 (70% of yield point), and that the pore space of all sub-grade soil below the

---

[32] Soils Engr. and Chf. of Laboratory, The Central Nebraska Public Power and Irrig. Dist., Ogallala, Nebr.

2-ft depth should not be greater than 40 per cent. Assuming a true specific gravity of 2.65, the dry weight of the soil below the 2-ft depth would be about 99 lb per cu ft. Assuming a true specific gravity of 2.65 and a lower plastic limit of 18% moisture, the dry weight of the soil with a factor of safety of 1.43 above the 2-ft depth would be about 124 lb per cu ft. It would be impractical, if not impossible, to obtain the latter weight by rolling, if the road-bed was to be constructed of a wind-blown silt loess material of uniform grain size. The only practical way to obtain this density would be by using suitable admixtures, which immediately brings the question of economy into the picture. The dry weight of 99 lb per cu ft is quite possible to obtain even in most poorly graded silts. It would seem to the writer that, in general, the factor of safety against water absorption as set by the author for the upper 2 ft may be somewhat high; however, for certain soils, it may be entirely practicable and satisfactory. It is impossible to lay down "hard-and-fast" rules that are applicable to all soil types. Certain general conditions undoubtedly apply to all soils. When used in a road-bed, however, each should be studied in detail and the various requirements modified to fit the individual soil.

The author is to be commended for presenting a definite method to follow in the design of road-beds. Such a method should tend to reduce the practice of "hit and miss" which has existed, all too often, in the past.

BERT MYERS,[33] ESQ. (by letter).—The highway engineer concerned with the economics of highway design will be interested in the limits suggested by Mr. Mullis for the physical properties of a satisfactory road-bed, and the cost of building a structure that will meet these requirements. He will also be interested in learning whether soil to which these properties have been imparted will continue to possess these properties after being exposed to varying conditions of temperature, stress, and opportunity for the absorption of moisture (see Table 4).

It is suggested that the road-bed should have an elastic limit of not less than 200 lb per sq in. The method for determining this elastic limit is not described. If it is to be determined by subjecting a small sample of soil, such as might be cut from the road-bed, to compression without horizontal restraint, this value would seem to be high, and difficult and expensive to attain.

It is suggested that the pore space in parts of the road-bed more than 2 ft below the sub-grade should not exceed 40% of the volume. This limit seems entirely practicable and reasonable. Another suggestion is that the pore space in the upper 2 ft of the road-bed be reduced to such an extent that its theoretical water capacity is not greater than 70% of the lower plastic limit of the earth used.

The Bureau of Soils Surveys, Iowa State Highway Commission, has conducted some studies to determine the probable behavior of soils in such a condition under field conditions (see Table 5). Samples have been taken from stabilized gravel base courses and their density and moisture content determined. The results of these studies indicate that this material, which had a distribution of particle sizes and degree of compaction such that the theoretical water capacity was below the limit suggested by Mr. Mullis, did not become less dense or absorb moisture when exposed to the conditions existing on the road. Samples taken from bases that contained 8 to 10% of moisture at the time they were constructed, were found to contain from 3 to 7% moisture two years later. This was true even where the moisture content of the subgrade soil, immediately beneath the base material, was as high as 24 per cent.

---

[33] Engr., Materials and Tests, Iowa State Highway Comm., Ames, Iowa.

A laboratory study along this same line was conducted as follows: Samples of three different soils common in Iowa, and mixtures of these soils with pit-run gravel, were formed into cylindrical specimens 4.5 in. in diameter by 9 in. high. The specimens were compacted to the highest density that seemed practicable with present road-building equipment. The specimens were moulded in rubber tubes which covered the specimens throughout the test. The lower end of the specimen was held in the tube by a perforated metal disk and blotting paper. The specimens were frozen in a freezing chamber and then thawed in the laboratory air with their lower ends immersed in water. The freezing and thawing treatments were alternated ten times. The volume and weight of each specimen were determined after each alternation. The results of this series of tests are given in Table 4.

TABLE 4.—Results of Freezing and Thawing on the Density and Moisture Content of Soil Specimens

Specimen	Composition (Percentages)		Percentage passing a No. 40 sieve	Original Condition		Condition After Freezing and Thawing		Plastic limit	Water capacity*
	Clay	Gravel		Density	Percentage of water	Density	Percentage of water		
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
A	Loess		100	1.84	15.1	1.73	20.4	19.4	89

G	13	87	30	2.17	8.3	2.18	8.3	14.1	60

* Percentage of plastic limit.

It will be noted that specimens in which the theoretical water capacity was greater than 70% of the lower plastic limit of the material (Column (10), Table 4) decreased in density and increased in moisture content under the test procedure. In these specimens the final moisture content was slightly greater than the lower plastic limit.

Specimens with theoretical water capacities of less than 70% of the lower plastic limit of the material did not decrease in density or gain materially in moisture content during the test. Specimens that did not decrease in density or increase in moisture content were composed of mixtures of soil and pit-run gravel.

The values in Column (4), Table 4 would indicate that, in order to make these characteristic Iowa soils comply with the suggested requirement, they

would need to be mixed with a sufficient quantity of coarser material to reduce the percentage passing the No. 40 sieve to about 40. In some localities, the cost of importing such a proportion of coarse material and mixing it with the soil locally available would be very great. This suggests that it might be cheaper to use the local materials to produce the best road-bed possible without the addition of coarser materials, and make up for the deficiency in the road-bed by constructing a stronger surface course.

Mr. Mullis has made a valuable contribution to the literature on the subject of the design of road-beds by presenting a paper in terms with which every engineer is already familiar.

E. NEIL W. LANE,[34] JUN. AM. SOC. C. E. (by letter).—Settlement of a stabilized road-bed will occur as erosion proceeds and as the road-bed approaches the natural condition of top soil. The rate and amount of settlement will naturally vary as the intensity and frequency of the erosional processes.

Since all roadway economics is based on the economical life of the wearing surface, it is at once apparent that the most desirable road-bed is one that will serve its useful life over a period equal to the economical life of the wearing surface. This implies, of course, that it is quite as necessary to give the same careful attention to the design of the road-bed as it is to the layout of the surface course. Little information is available, it seems, as to the useful life of different stabilized road-beds. The effect on the useful life of the various weather factors, the type of surface protection (as under paving or forming its own wearing surface), the location of the road-bed (as to slopes and depths), and the amount and types of loads have been scarcely questioned as far as accurate detailed study is concerned. Soil stabilization is a young science, and there is naturally much confusion in classifying and interpreting the results of such existing examples and studies as have been made and in setting proper questions for the basis of future studies. The latter are of utmost importance at this time, especially since the most valuable tests are the results of experience under scientific conditions.

In this paper, Mr. Mullis has raised several open questions and has collected and interpreted a great mass of fundamental data. He is to be commended for his painstaking efforts and for the general and basic perspective from which he has viewed the subject. The use of available materials and economical design seem to be underlying key-notes of the paper.

Many state specifications require the control of moisture and pore space but make little or no provision for placing the soil according to its ability to perform a service. Quite often they require that all the embankment be compacted to within 90% of the optimum compaction as shown by the Proctor density test. In doing this, it is generally found desirable to keep the moisture content slightly below (rather than slightly above) the optimum moisture as determined by the Proctor method, this being due to the fact that the usual construction equipment works more efficiently under these conditions. It would be better, the writer believes, to specify that the main body of fills be compacted to a stated lower density limit or such higher density as may be obtained by compacting the fill with a standard procedure and using a moisture content equivalent to 80% of the lower plastic limit, as shown by Atterburg's tests. Atterburg's tests are simple and thoroughly reliable, as have been proved. Moreover, it is believed that they are more adaptable to rapid field use in unskilled hands and with a minimum of equipment. Atterburg's tests do not allow as much variation of method and results as does the Proctor method.

---

[34] Junior Engr., U. S. Dept. of Interior, National Park Service Eng. Div., Omaha, Neb.

The use of a sheepsfoot roller is obviously better than the smooth-wheeled roller for use on the major portion of a fill, although the latter is necessary at and near the surface. The specifying of the two types of rollers for each project is a nicety to be developed by the future.

As a result of present-day experiences with field conditions and specifications, it would seem desirable to propose certain changes in the control of the construction of stabilized road-beds for the sake of a cheaper construction cost for an equivalent road-bed as far as useful life is concerned. These propositions are not as economically important for shallow cuts and fills as they are for heavy earthwork and side-hill construction.

It has been noticed that many road-bed troubles occur at transition points between a cut and the adjacent fill. This is undoubtedly caused by the rapid change in thickness and density of the road-bed at such points. In the case of rigid pavements an extreme condition can be shown for the purpose of illustration, although the results are noticeable in the non-rigid surfaces with a more deteriorating effect.

Assuming that the span between suitable bearing in cut and fill is the practical equivalent of two slab lengths of pavement and that the joint between these slabs is approximately over the thinnest portion of the stabilized road-bed, it is easily seen how undesirable variations in the density of this thin portion of the road-bed can cause serious surface misalignment in the case of rigid paving and a gradual disruption in the case of the non-rigid surfaces.

To overcome this difficulty it would seem desirable to excavate the ends of a cut first to such a depth as is necessary to obtain a natural soil with suitable density, or to excavate to some depth as would seem judicious, and replace this soil with stabilized material. The material excavated at the ends of the cut should be hauled to the deepest portion of the fill, and replaced by soil from the middle of the cut. This eliminates duplicate hauling but necessitates an additional handling charge which the writer believes would be more than offset by a decrease in maintenance and replacement expenses.
